ABSORPTION ENHANCERS

Jean Paul Remon

Ghent University, Ghent, Belgium

INTRODUCTION

There is enormous literature on the use of absorption enhancers. Here, the most important absorption enhancers for topical, transdermal and mucosal drug delivery are reviewed.

TOPICAL AND TRANSDERMAL

It is generally accepted that the bioavailability of most topically applied drugs remains low. Various methods to increase this bioavailability have been used. One of the approaches is the use of absorption enhancers, and over the years, there has been a great interest in new chemical absorption enhancers. An absorption enhancer should be pharmacologically inert, nontoxic, have a rapid and reversible onset of action, be chemically and physically compatible with other formulation compounds, and be cosmetically acceptable (1). Of course not all absorption enhancers possess all of these characteristics, and a benefit-to-risk evaluation will determine the choice of a molecule as an absorption enhancer. The range of absorption enhancers that has been researched is large. Thus, overview of the most researched compounds is presented.

Alcohols and Polyols

Some solvents are able to remove lipids from the stratum corneum, and several topical preparations (e.g., gels) and transdermal reservoir systems contain high concentrations of ethanol capable of modifying the lipid content of the skin (2). Solvents, such as ethanol, but also others such as propylene glycol, *N*-methylpyrrolidone, and Transcutol™, might also increase the drug flux through the skin by increasing the solubility of the permeant in the skin. It has also been suggested that the activity of propylene glycol results from solvation of α -keratin within the stratum corneum, hereby promoting permeation by reducing drug-tissue binding.

Amines and Amides

Some excipients might intercalate into the structure of lipids of the skin and disrupt the ordered packing making so the structure more fluid and influencing positively the diffusion coefficient. Azone® and its analogues have been widely studied in that respect, and it has been shown that the hydrogen bonding between the polar head group in Azone® probably interacts with the skin ceramides (3). Godwin et al. (4) compared the penetration-enhancing ability of a wide range of pyrrolidone compounds, including those with different chain lengths and functional groups. Using hydrocortisone as a model drug, these authors suggested that *N*-dodecyl-2-pyrrolidone and its acetate analogue were the two most effective penetration enhancers using in vitro hairless mouse skin model. Several studies dealt also with the mechanism of action of Azone® and its analogues. Compounds with short alkyl chains, such as *N*-methylpyrrolidone, seemed to have no effect on the phase transition temperature and probably work through its action of solvency rather than through a structural change of the skin barrier function. Using multilamellar DDPE liposomes, Hadgraft et al. (3) showed that their phase transition temperature was lowered by the Azone and its analogues in the same rank order as their enhancing abilities. This indicates that the modifier activity might be related to the fluidising effect on the lipid lamellae.

Studies involving the structure activity relationship of several groups of enhancers showed that the presence of a cyclic structure in the molecule plays an important role in the activity determination of the enhancers. In addition, the greatest barrier disruption activity was recorded for compounds with long alkyl chains between C₈–C₁₆ (5). Unfortunately, these molecules show also irritating potentials (6). Recently, Hadgraft (7) described some new molecules with similar structures but with low irritation potential.

Urea promotes transdermal permeation by facilitating hydration of the stratum corneum and the formation of hydrophilic channels (8).

Fatty Acids

The perturbation of the intercellular lipid bilayers in the stratum corneum seems to be the most important reason

for the enhancing activity of fatty acids such as oleic acid. Oleic acid has been described to decrease the phase transition temperatures of the skin lipids with a resultant increase in motational freedom—or fluidity—of these lipids (9).

Terpenes

Mono- and sesquiterpenes are known to increase percutaneous resorption by increasing the diffusion in the stratum corneum and/or disruption of the intercellular lipid barrier (10, 11). It has been shown that there is a major difference between different types of terpenes: e.g., it was shown that *d*-limonene did not disrupt the intercellular bilayers, whereas 1-8-cineole seemed lipid disruptive at physiological temperatures (12).

Menthol also has been described as a potential penetration enhancer due to its preferential distribution into the intercellular spaces of the stratum corneum and its possible reversible disruption of the intercellular lipid domain (13).

Esters

A typical example of an ester acting as a penetration enhancer is isopropyl myristate. Isopropyl myristate might show a double action: influence on the partition between vehicles and skin by solubilization and disruption of lipid packing, thus increasing the lipid fluidity (14, 15).

Sulfoxides

Dimethylsulfoxide (DMSO) has been found to be a potent enhancer, but unfortunately high concentrations which produce irreversible skin damage, erythema, and wheals, are required to obtain a desired effect. Recently, novel molecules were produced by modifying DMSO, by replacing the oxygen atom with a nitrogen atom that was substituted with an arylsulfonyl, aroyl, or aryl group. The *S*, *S*,-dimethyl-*N*-(4-bromobenzoyl)iminosulfurane produced the highest activity. But these compounds require more activity and toxicity studies, especially in less permeable models such as the human skin (16).

Cyclodextrins

Cyclodextrins can form inclusion compounds with an increase in solubility of lipophilic compounds, but they

seemed less effective alone than in combination with fatty acids and propyleneglycol (17).

Surface Active Agents

The effect of surface active agents on the skin barrier function depends on the agent's chemical structure. In general, anionic surfactants tend to be more effective than cationic ones, whereas nonionic surfactants are considerably less effective. Most anionic surfactants can induce swelling of the stratum corneum, as well as uncoiling and stretching of α -keratin helices, thereby opening up the protein controlled polar pathways (18).

The impact of anionic surfactants is a function of the alkyl chain length of the molecule. A maximum was observed for surfactants having a linear alkyl chain of 12 carbon atoms (e.g., sodium lauryl sulphate). Unfortunately, anionic surfactants are reported to be irritative. Nonionic surfactants might increase the membrane fluidity of the intercellular regions of the stratum corneum (e.g., Brij®) and may extract lipid components and additionally, though of minor importance, they might interfere with keratin filaments and create a disorder within the corneocytes (19). It should be emphasized that surfactant form micelles which, if used above their CMC, might negatively influence the drug bioavailability.

Other Enhancers

Other potential penetration enhancers have also been described, such as *N*-acetylprolineesters (20) and glyceryl monocaprylate/caprate (21).

It should be emphasized that the activity of any enhancer should be evaluated in terms of function of the vehicle used and that the selection of the combination enhancer-vehicle is a function of the final therapeutic objectives.

(TRANS)MUCOSAL PERMEATION ENHANCERS

At all mucosal sites, the coadministration of absorption enhancers is normally necessary to achieve therapeutic relevant plasma levels of (large) hydrophilic molecules such as peptides or proteins. Table 1 gives an overview of the most used and researched absorption enhancers and their possible mechanism of action.

Next, an overview is given of the most used transmucosal drug delivery routes and the use of permeation enhancers in each of them.

Table 1 Most used and researched mucosal permeation enhancers

Type	Examples	Mechanism of action
Synthetic surfactants	Laureth-9 sodium lauryl sulphate polysorbate 20 and 80 PEG-8 laurate sorbitan laurate glyceryl monolaurate saponins (e.g., Quillaja saponins)	membrane interaction extraction of membrane proteins and lipids solubilization of peptides
Bile salts	sodium deoxycholate sodium glycocholate sodium fusidate sodium taurodihydrofusidate	denaturation of proteins decrease of mucus viscosity decrease of peptidase activity solubilization of peptides formation of reversed micelles
Fatty acids and derivatives	oleic acid caprylic acid lauric acid palmitoylcarnitine	fosfolipid acylchain disruption
Chelators	Na ₂ EDTA citric acid salicylates	Ca ²⁺ complexation (influencing tight junctions)
Inclusion complexes	cyclodextrins and derivatives	increasing peptide stability increasing solubility enzyme inhibition
Other agents	Azone [®]	lipid structure disruption

Oral and Buccal Mucosa

There are clear differences between the oral mucosal membrane and other epithelial membranes of the intestine, nasal cavity and rectum. The oral mucosal membranes are less keratinized than the skin membranes and show a more loosely packed intercellular lipid domain. In terms of function of the absorption enhancement through the oral mucosal membrane, it can be said that it occurs principally through the lipid-filled intercellular spaces. One could suggest that the mechanism of increasing lipid fluidity of intercellular lipids, as indicated previously for the skin, should also apply for the oral mucosal membranes (22). As has been reported in the case of skin, other mechanisms can be applied here. For example, sodium deoxycholate appeared to denature and extract proteins from rabbit buccal mucosa and affected membrane lipids and inhibited proteases.

There are only a limited number of studies comparing the systematic changes in the structure of enhancers and

their influence on the oral mucosal membranes. For example, for insulin absorption in rats, it was shown that sodium glycocholate, laureth-9, sodium laurate, and sodium lauryl sulphate were approximately equipotent. Several nonionic surfactants having a C₁₂ hydrophobic tail were much less effective (23, 24).

A study related to the buccal bioavailability of testosterone indicated the absorption enhancing effect of hydroxypropyl-β-cyclodextrine with a relative bioavailability of 165% versus the administration without absorption enhancers. This effect was probably due to an increased solubility of testosterone, although cyclodextrins might also extract lipids from the intercellular matrix (25). In the same study, sodium tauro-24,25-dihydrofusidate and sodium deoxycholate did not show any enhancing properties.

Nasal Mucosa

Many papers have been published on the use and efficacy of absorption enhancers for nasal peptide and protein

delivery. The enhancing effect of bile salt seemed dependent on its lipophilicity: The bioavailability of gentamicin increased with increasing lipophilicity of trihydroxy bile salts (cholate > glycocholate > taurocholate), and the enhancement of nasal insulin bioavailability followed the rank order of deoxycholate, chenodeoxycholate, and cholate. However, most studies reported severe damage of bile salts to the mucosa. Deoxycholate had the most ciliotoxic effect, whereas taurocholate had the least ciliotoxic effect (26). In the case of dihydrofusidates, a dose-dependent increase in bioavailability was reported for peptides such as insulin.

A number of dihydrofusidate derivatives have been synthesized in order to evaluate the structure-enhancement relationship. Acidic derivatives achieved a higher enhancement than basic derivatives, but the safety of dihydrofusidates remains a contradictory issue and some structural damage to the mucosa has been reported (27).

In the past years, much research has concentrated on the use of cyclodextrins to enhance bioavailability of peptides and proteins especially because of their mild and reversible effect on the nasal mucociliary clearance (28).

Among the cyclodextrins, the use of DM β CD was shown to have the highest effect on the transnasal bioavailability of insulin in rats. Several studies reported on their concentration-dependent effect. Besides for peptides, the methylated β -cyclodextrins have shown to be useful in nasal delivery of lipophilic drugs. The toxicological profile of dimethyl β -cyclodextrins and of randomly methylated β -cyclodextrins appeared excellent. Attention should be paid, if possible, on bioavailability differences between animal and human models.

Vaginal Mucosa

Laureth-9, lysophosphatidylcholine and palmitylcarnitine chloride were found to be highly effective absorption enhancers, but all induced epithelial damage (29). Insulin was also administered to ovariectomized rats, and the coadministration of sodium taurodihydrofusidate, laureth-9, lysophosphatidylcholine, and -glycerol significantly increased hypoglycemia. Lysophosphatidylglycerol showed only minor damage of the vaginal epithelium, in contrast to the other absorption enhancers used (30). The combination of lysophosphatidylcholine and starch microspheres showed promising insulin bioavailability results (31).

Deoxycholate and quillajasaponins were reported to have a positive effect on the vaginal absorption of calcitonin (32).

Rectal Mucosa

Due to a combination of poor membrane permeability and metabolism at the site of absorption, rectal bioavailability of peptide and proteins is low. As in other mucosal bioavailability testing, insulin is the most studied polypeptide with respect to rectal absorption.

Sodium salicylate and 5-methoxysalicylate increased the absorption of insulin (33). Sodium glycocholate was more effective than sodium taurocholate but less effective than sodium-deoxycholate and PE-9-lauryl ether in enhancing rectal insulin absorption in rabbits (34). The role of disodium EDTA in the enhancement of rectal drug absorption, along with the damaging effects on the rectal mucosa, has been described for several drugs (35, 36).

Bile salts were also used for the enhancement of drug absorption, but several studies indicated severe damage due to their use in rectal drug delivery (37). Sodium tauro-24, 25-dihydrofusidate (STDHF) had a positive effect on the availability of cefoxitin, vasopressine, and insulin in rats (38).

The possible use of mixed micelles (e.g., made of unsaturated fatty acids and monoglycerides) has been shown for the enhanced rectal absorption of several compounds, including α and β interferon and insulin.

Pulmonary Absorption Enhancers

Only a few studies are available related to the effect of known absorption enhancers on the pulmonary absorption of poorly absorbable drugs, including peptides and proteins.

It was reported that oleic acid, oleyl alcohol, and Span 85 can increase the transfer rate of disodium fluorescein in isolated rat lungs (39). Pulmonary insulin absorption was reported to be increased in the presence of glycocholate and Span 85 (40). Fluorescein isothiocyanate, insulin, and a calcitonin analogue were better absorbed when coadministered with *n*-lauryl β -D-maltopyranoside, sodium glycocholate, and linoleic acid mixed micelles (41). The same authors, however, reported on the toxicity of *n*-lauryl β -D-maltopyranoside. A large number of questions are still remaining, such as why sodium caprate enhances the bioavailability of phenol red and isothiocyanate-labeled dextrans but not of insulin and a calcitonin analogue.

Hydroxypropyl- β -cyclodextrin and especially dimethyl- β -cyclodextrin have been shown to enhance the pulmonary bioavailability of insulin in rats, and indications were found of a relatively low acute mucotoxicity (42).

Table 2 Some of the commonly used intestinal absorption enhancers

Bile salts	Sodium cholate, sodium deoxycholate
Nonionic surfactants	Polysorbates and polyoxyethylene alkyl esters and ethers
Ionic surfactants	Sodium lauryl sulphate and dioctyl sulfosuccinate
Fatty acids	Sodium caprate, oleic acid
Glycerides	Medium-chain glycerides, phospholipids
Acyl carnitines	Palmitoylcarnitine
Chelating agents	EDTA
Swellable polymers	Polycarbophil and chitosan

Intestinal Absorption Enhancers

The optimization of oral bioavailability is of common interest because low bioavailability is often the cause of variable and poorly controlled clinical and toxic effects. This is of major importance for polar molecules such as peptides and proteins (43).

Table 2 reviews the most commonly described compounds to enhance intestinal absorption and indicates some examples (44).

It should be emphasized that absorption enhancers might act selectively on some parts of the GI tract, and this fact implicates that the formulation will play a major role in the optimal delivery of drug and absorption enhancers.

Bile salts have proven to act very differently on the intestinal absorption of drugs. In some cases, the drug absorption was reduced due to micelle formation, whereas in other cases, the absorption was enhanced due to intestinal membrane disruption caused by the solubilization of phospholipids or by Ca^{2+} complexation (45–47).

Nonionic and anionic surfactants haven been shown to be able to enhance the intestinal absorption of drugs. Some studies have shown that in the area of nonionic surfactants ethers were more effective than esters, but this phenomenon was not always confirmed. There is an indication that the surfactants cause membrane damage, which can be correlated with their enhancement activity (48). It has been shown that some tensioactive agents might influence tight junction permeability (49).

Fatty Acids

Fatty acids increase intestinal absorption via their influence on the paracellular and transcellular transport route. Most interesting results were obtained with lauric

acid, palmitic acid, caprylic acid, and oleic acid or their salts. Cytotoxic effects of fatty acids are concentration dependent long-chain unsaturated fatty acids especially can cause epithelial cell damage (50–52).

Glycerides

Medium-chain glycerides (mainly C_8 – C_{10}) are known to increase the intestinal absorption of poorly permeable drugs, mono- and diglycerides, especially, improve bioavailability, and it is believed that mainly transcellular permeation is increased.

It should be emphasized that the formulation plays an important role in the effect of these glycerides (emulsification, enteric coating, etc.) The main advantage of these products is their general acceptance for use in oral drug administration (53, 54).

Finally, it should be noted that during the last decade both weakly crosslinked poly(acrylic acid) derivatives and chitosan derivatives were described as safe penetration enhancers for hydrophilic compounds especially as they can trigger mechanisms of tight junction opening of mucosal tissues and did not show acute toxicity. Poly(acrylic acid) derivatives were shown to have excellent mucoadhesive properties and can inhibit the activity of gut enzymes, such as trypsin, chymotrypsin, and carboxypepsidases (55, 56). Chitosan salts and N_1 -trimethylchitosan chloride revealed to be potential absorption enhancers for nasal absorption of calcitonin and insulin and for the intestinal absorption of buserilin (57).

ABSORPTION OF DRUGS

Peter G. Welling

University of Strathclyde, Glasgow, Scotland

INTRODUCTION

In the first edition of this encyclopedia the section on absorption covered a range of topics that included discussion of the cell membrane, parenteral and enteral absorption, clinical factors, and pharmacokinetic characterization of absorption.

During the intervening time many of these areas have changed, some more than others. There also have been changes in emphasis, reflected particularly in the rapidly expanding interest and discoveries in membrane penetration, exploitation of various dosage routes, formulation factors, and absorption enhancers.

Emphasis in this section will reflect these activities. In order to conserve space, the pharmacokinetic treatment of drug absorption has been omitted.

OBJECTIVES OF DRUG ABSORPTION

Absorption may be defined as the process by which a compound penetrates one or more biological membranes to gain entry into the body. Absorption is not to be confused with bioavailability, which describes entry of administered compounds into the systemic circulation. For some drugs and dosage routes, absorption and bioavailability may be identical, i.e., after intravenous (IV) dosing. However, in many cases they are not. For a drug that does not undergo any metabolic transformation between an immediate postabsorption site and entry into the systemic circulation, absorption and bioavailability are likely to be the same. All of the absorbed drug enters the systemic circulation. This is regardless of any drug that may be degraded or changed in some other way, i.e., preabsorption.

On the other hand, for any drug that is degraded at a point between the postabsorption site and entry into the systemic circulation, the systemic availability—bioavailability—will be less than the absorption. An orally administered drug that undergoes extensive first-pass hepatic clearance may give rise to poor oral bioavailability despite being efficiently absorbed from

the gastrointestinal (GI) tract into the splanchnic circulation.

The pharmacologic activity profile of a systemically active drug is a function of its intrinsic activity and of the concentration profile that is achieved in the circulation. The speed of onset of action and the intensity and duration of activity are functions of the drug concentration profile.

The speed of onset of drug action is determined by the rate of drug absorption. Extreme cases are the use of bolus IV injection, which yields immediate and usually maximal pharmacologic effect, and slow controlled release, not necessarily by the oral route, where the onset of action is deliberately prolonged to achieve a desired therapeutic profile.

The intensity of pharmacologic effect is generally a function of the concentration of drug achieved in the circulation. Actual pharmacokinetic/pharmacodynamic relationships are often complex, but it is reasonable to generalize that higher circulating drug concentrations yield greater effect.

The levels of circulating drug that are achieved are a function of dose, absorption efficiency, overall bioavailability, distribution, and also clearance. The major determinant of drug distribution volume is its lipophilicity. As lipophilicity increases, so does the ability of the drug to cross biological membranes and move into extravascular environments, particularly into fatty tissue and the central nervous system (CNS).

Many drugs bind to plasma proteins, in particular to plasma albumin. Although binding of drugs to plasma proteins is dynamic and reversible, any drug that is bound at a particular time is necessarily confined to the plasma volume and thus cannot participate in extravascular distribution.

The last factor affecting circulating drug levels is clearance. The faster a drug is cleared from the circulation as a result of metabolism or any other process (i.e., the shorter its elimination half-life) the lower are its circulating levels. High circulating levels are less likely to be achieved with a high clearance drug than with a low clearance drug, and accumulation of a high clearance drug in the circulation with repeated dosing is unlikely.

Thus, the phenomenon of drug absorption is only one, albeit an important one, of several factors that determine

a drug profile in the circulation. It is important to understand all of these factors before drug profiles, and in particular pharmacokinetic/pharmacodynamic relationships, can be fully characterized, particularly in a predictive sense.

All of the above factors are functions of the physical and chemical properties of a drug. While distribution and clearance are affected only by drug properties and cannot generally be altered except by introducing some kind of interaction, drug absorption and bioavailability are often markedly influenced by route of administration, dosage form, and coadministration of other substances. Some of the major thrusts of pharmaceutical research during the last two decades have been devoted to these latter issues.

DOSAGE ROUTES

A required drug absorption profile is achieved by a variety of dosage routes. These routes may be divided into parenteral and enteral. Due to the importance of the various routes of administration in drug delivery, and of recent advances in optimizing route-dependent drug delivery, they are briefly reviewed here.

PARENTERAL ROUTES

Parenteral delivery routes are those that do not give rise to drug absorption into the splanchnic circulation. Thus, they avoid the possibility of hepatic first-pass metabolism. It should be noted that some parenteral routes do not avoid other first-pass metabolism effects (e.g., pleural metabolism for some inhaled drugs). Some major parenteral drug delivery routes are intra-arterial, intrathecal, intravenous, intramuscular, transdermal, intranasal, buccal, inhalation, intraperitoneal, vaginal, and rectal.

Intra-arterial

Intra-arterial injection is used to deliver drugs directly to organs, for example, in cancer chemotherapy, and in the use of vasopressin for GI bleeding. Intra-arterial carmustine is effective to treat brain tumors (1) and pelvic intra-arterial actinomycin D is used for malignant trophoblastic disease (2).

Intra-arterial drug administration has potential safety implications. Embolization, arterial occlusion, and localized drug toxicity have been reported.

Intrathecal

Injection directly into the cerebrospinal fluid (CSF) ensures complete CNS bioavailability for drugs that cannot cross the blood-brain barrier. This dosage route is used to treat serious CNS infections such as meningitis and ventriculitis, and with such agents as mepivacaine and prilocaine for spinal anesthesia. Drugs injected intrathecally initially distribute into approximately 140 ml of CSF, thus producing high concentrations in the CNS with low risk of systemic toxicity.

Intravenous (IV)

IV administration introduces drug directly into the venous circulation. The shape of the resulting circulating drug profile is determined by the size, rate, and duration of injection. IV bolus is used for immediate therapeutic effect, typically for general anesthesia and for treatment of cardiac arrhythmia. IV dosing is popular for preclinical testing of compounds during drug development and also as a standard to determine absolute bioavailability from other dosage routes.

Intramuscular (IM)

Following intramuscular (IM) administration, drugs must cross one or more biological membranes in order to enter the systemic circulation. Intramuscular injection is used mainly for drugs and vaccines that are not absorbed orally, for example, aminoglycosides, insulin, and hepatitis vaccine. The IM route is often used for sustained medication and specialized vehicles, such as aqueous suspensions, oily vehicles, complexes and microencapsulation, which has been developed for slow delivery of drugs by this route (3).

Transdermal

Since the introduction of transdermal scopolamine (4), many transdermal delivery systems have been developed for systemic activity. Major advantages claimed for this drug delivery route include continuous release of drug over a specified period, low presystemic clearance, facile drug withdrawal by simply removing the device, and good patient convenience and compliance.

Some disadvantages relate to barrier properties of the skin, skin reactions, and the relatively large dose size. Transdermal delivery is a realistic option only for drugs generally given in small doses (<10 mg) and which have good membrane penetration. Drugs currently approved for transdermal delivery include clonidine, estradiol, nicotine, nitroglycerin, and scopolamine.

Intranasal

Intranasal administration may be used for local or systemic effects. Local effects include treatment of nasal allergies, rhinitis, and nasal congestion. Nasal delivery for systemic effects is established for a small number of drugs and is being examined for many others.

The sophisticated structure and specialized function of airways and membranes in the nasal cavity, and also the small surface area of this region, may limit its capacity for drug delivery. The effect of chronic drug exposure on the integrity of nasal membranes must also be considered. This problem may be compounded by the evident need for surfactants to achieve good systemic penetration with this dosage route.

Notwithstanding these factors, the physical characteristics of compounds for optimal intranasal absorption are the same as for other absorption routes. The drug must dissolve in the fluids of the nasal mucosa and must be sufficiently lipophilic to cross the membranes of the nasal epithelium. Nasal absorption is facilitated by the high permeability of small venules and capillaries associated with the nasal mucosa.

A variety of delivery systems have been described for nasal drug delivery, including drops, aerosols, nebulizers, and soluble matrices (5).

Small peptide molecules seem to be ideally suited for intranasal drug delivery. Vasopressin analogues and oxytocin are commercially available for intranasal dosage. Thyrotropin-releasing hormone agonists and antagonists, other vasopressin analogs, and peptides are being examined. Intranasal delivery of sex hormones has produced interesting results in animals. Intranasal delivery of insulin has been examined, but only with moderate success.

Buccal

Early recognition of buccal and sublingual absorption was manifested in the use of nitroglycerin by these dosage routes to treat severe headache and to relieve angina pectoris.

Drugs can be absorbed from the oral cavity itself or sublingually. Absorption from either route is rapid,

sublingual more so apparently because of greater permeability of sublingual membranes and rich blood supply. The mean pH of saliva is approximately 6 so that drug absorption, predominantly passive in nature, is favored for unchanged molecules, acids with pK_a values >3, and bases with pK_a values <9.

Compounds that are currently marketed or are being considered for buccal or sublingual routes include organic nitrates, barbiturates, papaverine, trypsin, prochlorperazine, benzodiazepines, buprenorphine, captopril, isoprenaline, oxytocin, and nifedipine. Oxytocin is currently the only peptide marketed in sublingual form. Sublingual steroids have been examined with moderate success.

Inhalation

When a substance is inhaled, it is exposed to membranes of the mouth or nose, pharynx, trachea, bronchi, bronchioles, alveolar sacs, and alveoli (Fig. 1). The lung has a potential absorption surface of some 70 m², a much larger surface than the small intestine. However, the lungs and their associated airways are designed to deny access of administered compounds to the highly absorptive peripheral lung surfaces. The system is designed to deny access to particulate matter. However, if compounds can reach the peripheral region of the lung, absorption can be very efficient.

Particle (droplet) size and velocity of application control the extent to which inhaled substances penetrate into airway spaces. Optimum size for deep airway penetration is 3–5 μ M. Large particles tend to deposit in upper airways.

Most inhalation devices deliver approximately 10% of the administered dose to the lower respiratory tract. A number of devices have been developed to increase lung delivery, and delivery of up to 21% has been

Fig. 1 The human respiratory tract.

reported with a pressurized metered-dose inhaler (6). Despite these advances, drug delivery via the lung is still inefficient.

Systemic availability of inhaled drugs may be inhibited by first-pass pulmonary metabolism. The lungs contain many drug metabolizing enzymes, including mixed function oxidases, monoamine oxidase, and esterases.

Several animal models principally the rat, rabbit, and dog, are used to study drug inhalation.

Intraperitoneal

Intraperitoneal drug administration is not common. It is used predominantly to administer compounds during preclinical discovery and development. Its clinical use is generally limited to chemotherapy for tumors with peritoneal involvement.

Peritonitis occurs frequently in renally impaired patients who are receiving continuous ambulatory peritoneal dialysis (CAPD). Peritonitis is often accompanied by systemic infection so that therapeutic levels of antibiotic are needed both in the peritoneal cavity and in the systemic circulation.

Drugs may be given orally or by injection in order to achieve adequate systemic levels in the hope of also achieving therapeutic levels in the peritoneal cavity. Alternatively, drugs may be administered directly into the peritoneal cavity with the objective of also achieving systemic levels by intraperitoneal absorption (7). To the author's knowledge, there is little definitive information on the relative merits of these alternatives.

Vaginal

The human vagina, a fibromuscular tube 10–15 cm long, extends upwards and backwards from the vulva to the lower uterine cervix. Blood is supplied to the vagina via the uterine and pudendal arteries, and is drained from the vagina by a rich plexus, which flows into the internal iliac veins. The surface of the vaginal epithelium is kept moist by cervical secretions. The pH of vaginal fluid is 4–5.

Vaginal drug delivery is used mostly for local effects, but vaginal absorption can give rise to rapid and efficient systemic delivery. Good systemic absorption, and also the ability of the vagina to retain delivery devices, has given rise to many vaginal dosage forms, in particular for steroid contraceptives. A large number of vaginal controlled release dosage forms are available, including vaginal rings and biodegradable microspheres.

Rectal

The human rectum is 15–20 cm long. It is normally empty and contains 2–3 ml of mucous fluid with pH 7–8. There are no villi and only a limited surface area of 200–400 cm² is available for absorption.

Blood and lymph vessels are abundant in the rectal submucosa. Veins from the upper rectum drain into the portal circulation, while veins from the middle and lower rectum drain directly into the inferior vena cava. However, there are extensive anastomoses among these veins so that precise anatomical differentiation is difficult. It appears that compounds absorbed from the lower rectum, in contrast to those absorbed from the upper rectum, avoid hepatic first-pass metabolism.

Rectal absorption is generally slower than oral absorption, but for some drugs, rectal absorption exceeds oral absorption presumably due to avoidance of first-pass metabolism after rectal delivery. This has been reported for morphine, metoclopramide, ergotamine, lidocaine, and propranolol. Human rectal systemic availability of the extensively metabolized drug lidocaine is 65% as compared to 30% after oral administration (8).

Rectal absorption of drugs from aqueous or alcoholic solutions is generally much faster than from suppositories. Nonsurfactant adjuvants, such as salicylates, increase rectal absorption of water-soluble drugs and also of high molecular weight compounds, such as insulin, heparin, and gastrin.

ENTERAL ROUTES

Enteral routes of drug absorption are from the stomach and the small and large intestine. Substances absorbed from these areas enter the splanchnic circulation and pass through the liver before entering the systemic circulation.

The GI tract is the site of absorption for most nutrients. Thus, the GI tract has evolved to facilitate absorption of substances. The peristaltic action of the stomach, secretion of enzymes and hydrochloric acid, the villi and microvilli of the intestine, as well as the rich blood supply and lymphatics in this region, all facilitate absorption. Enteral absorption is generally by far the most effective drug delivery route and, whenever possible, drugs are administered in this way.

Any orally absorbed compound is exposed to an absorption environment that is both friendly and hostile, depending on the compound and the patient. A brief review of the structure and physiology of the GI tract relative to drug absorption follows.

Fig. 2 Approximate pH values in the human gastrointestinal tract.

Physiology of the GI Tract

Figure 2 shows the pH of various regions of the GI tract. From the slightly acidic region of the mouth, a compound enters the more acidic region of the stomach. Acidity is a consequence of hydrochloric acid secretion by the parietal cells of the stomach. This plays an important role in food digestion by facilitating conversion of pepsinogens and zymogens to active proteolytic enzymes.

The acidic environment in the stomach tends to favor gastric absorption of acidic drugs provided the drugs are in solution. On the other hand, basic drugs tend to dissolve readily in the stomach but absorption may be prevented because the drug will be ionized and therefore not sufficiently fat soluble for efficient membrane penetration. The acidic environment in the stomach may give rise to reduced drug absorption due to acid-catalyzed degradation.

If a drug dissolves in the stomach or is a liquid, and if it is fat-soluble and acid stable, then it is likely to be absorbed efficiently from the stomach. Ethyl alcohol is a liquid that is completely miscible with water and sufficiently lipophilic to cross biological membranes. It is efficiently absorbed from the stomach.

After passing through the pyloric sphincter, a compound reaches the duodenum, jejunum, and ileum. These regions of the small intestine differ from the stomach with respect to pH, the presence of digestive enzymes, and the absorptive surface area. Excretion of alkaline bile into the duodenum raises the pH of the duodenal and more distal intestinal contents to 5–7. The change in pH from acidic to essentially neutral causes many changes that affect drug absorption. Enteric coatings that were impermeable in the

stomach will dissolve. Acidic drugs will dissolve more rapidly and yet the pH will not be sufficiently high to prevent dissolution or cause precipitation of weakly basic drugs.

GI Structure and Motility

The stomach is a pouch-like organ lined with a relatively smooth epithelial surface. Although compounds can be absorbed from the stomach, the contribution of this organ to overall enteral drug absorption is modest. The absorptive properties of the proximal small intestine are superior to those of the stomach or any other region of the GI tract. The rate at which compounds pass from the stomach into the small intestine is a rate-limiting step controlling drug absorption. Stomach motility is complex and is influenced by nervous and hormonal stimuli. Stomach emptying rate is a function of rhythmic contractions that have a frequency of approximately three per minute in a fasted person, and less when food enters the stomach.

Food passes from the stomach into the duodenum as a result of these rhythmic contractions. The heavier the meal and the higher the fat content, the longer it will take for a meal, and any drug that may be ingested with it, to pass into the small intestine. This process acts as a defense mechanism by which substances are prevented from entering the proximal small intestine and injuring the delicate absorptive surface of this region until they are reduced to a suitable consistency in the stomach.

Whereas solid food delays stomach emptying, liquids tend to accelerate the process. Acceleration results from activation of stretch receptors in the stomach wall. When the fluid is water, activation of the inhibitory receptors is stopped. This results in rapid emptying of stomach contents into the duodenum.

By far the most important difference between the proximal small intestine and the stomach is the nature of the mucosal surface of the epithelium. The mucosal surface of the small intestine is increased by finger-like projections, or villi, that arise from the folds of Kerckring, and in turn by microvilli that arise from the villi. These invaginations increase the surface area of the intestinal mucosa some 600-fold to approximately 200 m², and 1.0–1.5 L of blood passes through intestinal capillaries each minute. Corresponding values for the stomach are only 100 m² of surface area and a blood flow rate of 150 ml/min. Thus, the small intestine has a surface area approximately double that of the stomach and a blood perfusion rate 6–10 times faster. Both factors strongly favor more efficient absorption from the small intestine.

The villi and microvilli of the small intestine are lined by a sulphated mucoprotein, glycocalyx. Fluid trapped within the glycocalyx is stationary, and a series of thin layers, each progressively more stirred, extends to the bulk phase of the intestinal lumen. This series of unstirred layers has an effective thickness of 0.01–1.0 mm.

Molecules move within the unstirred layers by diffusion at a rate inversely proportional to the square root of molecular weight below 450, and inversely proportional to the cube root of molecular weight above 450. The glycocalyx is negatively charged, with counterions in the unstirred layer. If a substantial proportion of these cations is composed of hydrogen ions, as is often the case, then the microclimate within the brush border of the epithelium is likely to be acidic relative to the bulk phase. This may influence drug ionization at the membrane surface, and provides a basis for the “acid microclimate” frequently associated with the GI mucosa.

The length of time during which material stays in the small intestine is approximately 5 min in the duodenum, 2 h in the jejunum, and 3–6 h in the ileum. Material then enters the large intestine.

The large intestine does not have villi or microvilli at its mucosal surface. Its contents are neutral or alkaline. Therefore, absorption of drugs from the large intestine is less efficient than from the small intestine. The large intestine and colon contain an active bacterial microflora that can degrade foreign molecules that also tends to reduce absorption of drugs from this region of the GI tract.

GI Secretions

The rate of acid secretion into the stomach is controlled by parietal cells. Acetylcholine, histamine, and gastrin are important for regulation of hydrochloric acid secretion, and they act directly on parietal cells to enhance acid secretion rate.

Phases of gastric acid secretion

The basal rate of hydrochloric acid secretion varies diurnally, being highest in the evening and lowest in the morning. After ingestion of a meal, the rate of acid secretion in the stomach increases. The three phases of increased acid secretion in response to food are the cephalic phase (before food reaches the stomach), the gastric phase (elicited by the presence of food in the stomach), and the intestinal phase (elicited by input from the duodenum and upper jejunum).

Cephalic phase

The sight, smell, and taste of food elicit this phase. Acid secretion during this phase can be as much as 40% of the

maximum rate. Other stimuli sensed in the brain, in addition to those related to the presence of food, may evoke acid secretion through vagal impulses.

Gastric phase

The presence of food in the stomach evokes gastric secretion. The principal stimuli include distension of the stomach and the presence of amino acids and peptides. Distension of the stomach stimulates mechanoreceptors that bring about secretion of acetylcholine, hydrochloric acid, and gastrin.

Intestinal phase

The presence of chyme in the duodenum stimulates neuronal and endocrine responses that stimulate and later inhibit secretion of acid into the stomach. The stimulatory influences dominate when the pH of gastric chyme is above 3. However, when the buffer capacity is exhausted and the pH falls below 2, inhibitory influences dominate.

Gastric acid secretion may be regulated by several brain peptides, some of which may enhance secretion, while others may act centrally to inhibit secretion.

Gastric Juice

Gastric juice contains a mixture of secretions from surface epithelial cells and gastric glands. Salts, water, pepsins, intrinsic factor, and mucus are main components of gastric juice. Gastric secretions increase after a meal. Ionic composition of gastric juice is related to the rate of secretion. The higher the secretory rate, the higher the hydrogen ion concentration. The rate of gastric acid secretion varies among individuals. In humans, the basal rate is 1–5 mEq/h. With histamine or pentagastrin stimulation, acid output rises to 5–40 mEq/h.

Other Secretions

Bile, pH 7.8–8.6, is produced continuously in humans. Hepatic bile is concentrated and stored in the gall bladder between meals. It is ejected from the gall bladder and flows into the duodenum when food enters the intestine. The main constituents of bile are bile salts, bilirubin, end products of hemoglobin breakdown, the electrolytes sodium, chloride, and bicarbonate, cholesterol, phospholipids, and lecithin. The gall bladder contracts within 30 min after eating due to liberation of cholecystokinin. The most effective stimulus to this is food high in fat.

Bile salts, which are surface active, promote dissolution of lipophilic drugs and lipophilic drug formulations, enteric coatings, and waxy drug matrices. Bile salts may

also promote membrane permeability of lipophilic molecules through micelle formation and solubilization.

Pancreatic juice contains an alkaline fluid and enzymes, both of which empty into the duodenum. The alkaline pH contributes to neutralization of the acid that empties from the stomach. The enzymes amylase, lipase, trypsin, and chymotrypsin play major roles in the digestion of carbohydrates, fats, and proteins. Trypsin and chymotrypsin are secreted as inactive precursors and are converted to the active forms enzymatically.

As a result of proteolytic enzyme secretion into the duodenum, protein or peptide drugs, such as corticotropin, vasopressin, and insulin, are rapidly degraded and generally cannot be given orally. Secretory activity of the pancreas is under hormonal and neuronal control.

Intestinal secretions do not exist in the same sense as gastric, pancreatic, or biliary secretions. Nonetheless, large fluid fluxes take place throughout the intestine. Any secretions from the intestinal mucosa appear to have a lubricant and protective effect.

GI Blood Flow in Relation to Drug Absorption

Drugs may be transported away from the serosal side of the GI tract by one or both of two mechanisms. The GI tract is supplied by a blood capillary network from the splanchnic circulation. Drugs may also be taken up by the lymph vessels in the GI epithelium and carried by the lymphatic system that drains the abdominal area into the thoracic duct. Any drug that is absorbed via this system enters the systemic circulation directly and is not susceptible to first-pass hepatic metabolism. Despite the presence of both the blood capillary network and the lymphatic system, absorption of the great majority of drugs appears to occur predominantly via the capillary system associated with the splanchnic circulation.

The reason for this appears to lie in the relative flow rates of blood and lymph. The rate of blood flow in the splanchnic circulation is 1.0–1.5 L/min, or 30% of cardiac output. This rate may increase to 2 L/min after a meal. Lymph flow through the same region is only 1–2 ml/min, but may increase to 5–20 ml/min after a meal. Lymph flow in this region is thus 500–700 times slower than blood flow. Relatively fast splanchnic blood flow establishes virtual sink conditions on the serosal side of the GI epithelium and ensures a steep concentration gradient. These conditions promote efficient absorption into the bloodstream rather than into lymph.

Only a small number of drugs are absorbed via the lymph system. These include drugs with high molecular weights that cannot enter the capillaries and specific molecules such as steroids.

Hepatic First-Pass Metabolism

The majority of compounds absorbed from the stomach and intestines enter the splanchnic circulation. This leads to the portal vein, the liver, and then to the general circulation. Compounds absorbed via this route must therefore pass through the liver and will do so initially at a higher concentration relative to when they eventually distribute into the general circulation and elsewhere.

As hepatic metabolism is generally first order in nature, a large proportion of any orally administered drug that is highly and efficiently metabolized in the liver will be cleared during the initial first pass. A drug could be efficiently absorbed from the GI tract and yet poorly available to the general circulation as a consequence of first-pass hepatic clearance. Such high extraction drugs include acebutolol, alprenolol, desipramine, isoproterenol, and lidocaine.

ABSORPTION MECHANISMS

An orally administered drug must pass through a number of membranes in order to be absorbed into the systemic circulation. Many physiological membranes differ in structure and function. Despite this, there is general consensus regarding the basic structure of the cell membrane.

The Cell Membrane

The primary structure of the cell membrane, shown in Fig. 3 (9) is a 5-nm thick bimolecular lipid film that separates intracellular and extracellular fluids. The lipid is composed mainly of the phospholipids phosphatidylserine and phosphatidylinositol, and contains saturated and unsaturated fatty acids and sterols. The bilayer exhibits high permeability to hydrophobic molecules and low permeability to hydrophilic molecules.

The cell membrane is associated with intrinsic and extrinsic proteins. Intrinsic proteins are globular proteins that generally span the bilayer and are held within the membrane by hydrophobic and electrostatic interactions. The proteins can form channels, carriers, or pumps that enable polar molecules to cross the membrane.

Membrane Transport

Several mechanisms have been identified for drug transport across membranes. One of them is passive. The remainder utilize some type of carrier mechanism.

Fig. 3 Structural model of the cell membrane. The membrane is composed of a bimolecular leaflet of phospholipid with the polar head groups facing the extracellular and cytosolic compartments and the acyl groups in the middle of the bilayer. Integral membrane proteins are embedded in the lipid bilayer. Integral proteins are glycosylated on the exterior surface and may be phosphorylated on the cytoplasmic surface. Extrinsic membrane proteins, peripheral proteins, are linked to the cytosolic surface of the intrinsic proteins by electrostatic interactions. (From Ref. 9.)

Simple or Passive Membrane Transport

This mechanism, based primarily on lipid solubility and concentration gradient, is responsible for membrane transport of the great majority of drugs. The range of membrane permeabilities is very high. Typically, hydrophobic molecules have high partition coefficients, while hydrophilic molecules have low partition coefficients. The direction and rate of transport are determined by the concentration gradient of a substance across the membrane.

Molecules that are weak acids or bases cross membranes more readily when they are in the nonionized form. However, aqueous solubility is favored for the ionized form. In order to be available to cross any membrane, a drug must be in solution. This paradoxical requirement of both aqueous and lipid solubility is of particular concern in the area of drug absorption and presents a constant challenge in pharmaceutical formulation.

Transport Proteins

Many substances, particularly polar molecules, cross membranes at rates greater than those predicted from solubility and permeability data. Some can cross membranes against a concentration gradient. Unexpectedly high membrane permeability is related to transport proteins. Many transport proteins have been identified, cloned, and sequenced. Current knowledge has permitted

an operational definition of carrier proteins as channels, carriers, and pumps. The current state of the art in identification and characterization of these systems has been described by Wright (9).

Channels

Initial speculation on the existence of small aqueous pores in membranes was based on high membrane permeability of small polar molecules. For example, the permeability of water is 1000-fold more, and that of urea 10- to 100-fold more, than predicted. These types of observations led to the prediction of aqueous channels with radii of approximately 4 Å.

Water channels

The presence of water channels has been demonstrated by successful cloning of proteins that increase membrane water permeability. These have been expressed in erythrocytes and in cells of the renal tubule.

Ion channels

Evidence for ion channels in biological membranes was introduced in the 1970s. Possibly the most significant experiment was by Neher and Sakmann (10), who recorded single ion channel currents in muscle fibers. Many types of channels for sodium, potassium, calcium, and chloride ions have been described, and each has a specific conductance, ion selectivity, and probability of opening. Ion channel opening may be controlled by voltage or by ligand, and channels are thus designated voltage-gated or ligand-gated. Each of the ion channels has a specific pharmacology. Sodium channels are 12 times more selective for sodium than for other cations. Calcium channels are 1000 times more selective for calcium than for other cations.

Facilitated Diffusion

Facilitated diffusion is a simple mechanism proposed to explain transport of water soluble compounds. The main characteristics of this transport system are that membrane permeability exceeds that predicted from partition coefficients, transport occurs down a concentration gradient, transport is saturable, and competition occurs between isomers. Facilitated diffusion has been used to explain cellular uptake of sugars and amino acids.

Six human sugar transporters with different tissue distributions, substrate kinetics, and specificities have been identified. A number of facilitated amino acid transporters have also been identified in mammalian cells. System L,

which transports neutral amino acids, such as leucine and phenylalanine, is probably the best known of these.

Pumps

Pumps are proteins that can transport ions against electrochemical potential gradients using adenosine-5-triphosphate (ATP) as an energy source. Sodium–potassium pumps maintain intracellular sodium and potassium concentrations in animal cells and also control salt and water absorption by the epithelial cells in the intestine and kidney. The sodium–potassium pump transports three sodium ions out of the cell and two potassium ions into the cell at the cost of one molecule of ATP. The 3:2 coupling ratio results in net loss of sodium ions into the cell down an electrochemical gradient and maintains cell volume. Currently, considerable research is attempting to elucidate the structures of the various isoforms and subunits of sodium potassium pumps.

Cotransporters and Exchangers

There are many other examples of ions and ionized molecules accumulating in cells against their concentration gradient, such as uptake of iodine by the thyroid gland, accumulation of acids in liver cells, and absorption of sugars and phosphate by the small intestine. Recent studies have shown that these are governed by cotransport mechanisms. In all cases tested to date, sodium or hydrogen ion gradients are used to drive cotransporters, and these gradients are maintained by ion pumps. Glucose transport across the brush border of the small intestine is coupled with sodium transport, and uphill sugar transport is driven by the sodium gradient.

Cotransporters

Cotransporters use the sodium or hydrogen ion gradient to drive transport of a substrate. Many cotransporters have been described, cloned, sequenced, and expressed. The sodium–glucose cotransporter just described is one of these.

Other cotransporters facilitate the transport of other sugars, osmolytes, and amino acids. In humans, a disorder of intestinal glucose and galactose absorption is due to a defective sodium–glucose transporter.

Antiporters

The best characterized antiporters, or exchangers, are the chloride–bicarbonate, sodium–hydrogen ion, and sodium–calcium exchangers. The cellular sodium–hydrogen ion exchanger controls cell volume, pH, growth,

and sodium transport. Mammalian isoforms of these exchangers have been cloned and sequenced. Sodium–hydrogen exchangers play a dominant role in the regulation of intracellular calcium, and thus the force of contraction of the heart. The therapeutic effect of cardiac glycosides is probably related to decreased sodium–calcium exchange in the heart caused by a decreased sodium–hydrogen gradient across the cell membrane.

Permeability Glycoprotein

Permeability glycoprotein (p-glycoprotein) is an ATP-dependent efflux pump responsible for pumping substances out of cells. It is implicated in development of drug resistance in tumor cells. Localization of p-glycoprotein in the apical membranes of intestinal, liver, and kidney cells, and also at the blood brain barrier, provides potential for this pump to have a profound effect on drug absorption, distribution, and elimination, as well as in drug–drug interactions.

Pinocytosis and Endocytosis

Pinocytosis is a nonspecific process whereby a substrate enters a cell by invagination to form an intracellular vesicle. Receptor-mediated endocytosis occurs when substrate binds to a specific membrane receptor. Substrates ingested by cells in this way are stored in vesicles or degraded. Receptor-mediated endocytosis is involved in cellular uptake of immunoglobulin and low density lipoprotein.

FORMULATION FACTORS AFFECTING DRUG ABSORPTION AND ABSORPTION ENHANCERS

The chemical and physical properties of a drug and its formulation can affect drug stability and absorption characteristics.

Chemical Factors

A variety of chemical options can be used to improve the stability and systemic availability of drugs. For example, esters can be prepared of both acids and bases to produce more stable derivatives, which hydrolyse to the active parent once absorbed. The stability and solubility of both acids and bases tend to increase when they are in the form of salts. Typically, administration of soluble salts of penicillin give rise to higher circulating antibiotic levels

than the free acid. When the salt of a weak acid dissolves in the stomach, it generates a diffusion layer of relatively high pH which, in turn, promotes further dissolution. The same argument could theoretically be used for basic drugs. However, the pH effect in this case is swamped by the very low pH present in stomach fluids. Thus, salts of basic drugs are used primarily for handling and solubility rather than for improved dissolution.

Physical Factors

Different physical forms of a drug can affect its absorption. Typically, the crystal or polymorphic form, the state or nature of hydration or solvation, and physical size of drug particles may have considerable impact on the rate and extent of drug absorption.

Polymorphism and amorphism

Many compounds form crystals with different molecular arrangements, or polymorphs. These polymorphs may have different physical properties, such as dissolution rate and solubility. The vitamin riboflavin exists in several polymorphic forms, and these have a 20-fold range in aqueous solubility. Polymorphs that have no crystal structure, or amorphic forms, have different physical properties from the crystalline forms.

Absorption of many orally administered drugs is controlled by dissolution rate. Amorphous forms generally dissolve faster than crystalline forms because no energy is needed to break up the crystal lattice. For this reason, the amorphous form is often preferred over the crystalline form and several drugs, including hydrocortisone and prednisolone, are marketed in the amorphic form.

Solvation

During their preparation, drug crystals may incorporate one or more solvent molecules to form solvates. The most common solvate is water. If water molecules are already present in a crystal structure, the tendency of the crystal to attract additional water to initiate the dissolution process is reduced, and solvated (hydrated) crystals tend to dissolve more slowly than anhydrous forms. Significant differences have been reported in the dissolution rate of hydrated and anhydrous forms of ampicillin, caffeine, theophylline, glutethimide, and mercaptopurine. The clinical significance of these differences has not been examined but is likely to be slight.

Particle size

Particle size may play a major role in drug absorption. Dissolution rate of solid particles is proportional to surface

area, and hence to particle fineness. Particle size reduction has been used to increase the absorption of a large number of poorly soluble drugs, such as bishydroxycoumarin, digoxin, griseofulvin, nitrofurantoin, and tolbutamide.

Griseofulvin has extremely low aqueous solubility, and material of normal particle size gave rise to poor and erratic absorption. Microsize particles improve absorption, but it is improved even more when it is formulated in ultramicrosize particles as a monomolecular dispersion in polyethylene glycol.

Formulation Factors

Drug formulations are designed to provide an attractive, stable, and convenient method to use products. Conventional dosage forms may be broadly characterized in order of decreasing dissolution rate as solutions, solid solutions, suspensions, capsules and tablets, coated capsules and tablets, and controlled release formulations.

Solutions

Aqueous solutions, syrups, elixirs, and emulsions do not present a dissolution problem and generally result in fast and often complete absorption as compared to solid dosage forms. Due to their generally good systemic availability, solutions are frequently used as bioavailability standards against which other dosage forms are compared.

Solid solutions

The solid solution is a formulation in which drug is trapped as a solid solution or monomolecular dispersion in a water-soluble matrix. Although the solid solution is an attractive approach to increase drug absorption, only one drug, griseofulvin, is currently marketed in this form.

Suspensions

A drug in a suspension is in solid form, but is finely divided and has a large surface area. Drug particles can diffuse readily between the stomach and small intestine so that absorption is relatively insensitive to stomach emptying rate.

Similar to solutions, suspensions are useful for patients who have difficulty taking solid medication. Adjusting the dose to a patient's needs is easier with solutions and suspensions than with solid dosage forms. Liquid dosage forms, therefore, have several practical advantages besides simple dissolution rate. However, they also have some disadvantages, including greater bulk, difficulty in handling, and perhaps reduced stability.

Capsules and tablets

Capsules and tablets are the most common oral dosage forms. These formulations differ from each other in that material in capsules is less impacted than in compressed tablets. Once a capsule dissolves, the contents generally disperse quickly. The capsule material, although water soluble, can impede drug dissolution by interacting with the drug, but this is uncommon.

Tablets generally disintegrate in stages, first into granules and then into primary particles. As particle size decreases, dissolution rate increases due to increased surface area.

Tablet disintegration was once considered a sufficient criterion to predict *in vivo* absorption. This was proven inadequate, however, and dissolution is now recognized as a better criterion. Regulatory agencies now require dissolution rate data for all new oral formulations. The increasingly wide acceptance of dissolution as the best available *in vitro* parameter to predict *in vivo* absorption is reflected in the proliferation of such tests in official compendia.

Excipients: Along with active material contained in tablets and capsules, a variety of so-called inert ingredients are present, for example, starch, magnesium aluminum silicate, methylcellulose, carboxymethylcellulose, lactose, kaolin, talc, calcium sulfate, and magnesium stearate. Tablets may also have a variety of coatings to improve stability, taste, appearance, and drug release characteristics. Although considered to be inert, these additives can affect drug dissolution and absorption. Changing an excipient from calcium sulfate to lactose and increasing the proportion of magnesium silicate, increases the activity of oral phenytoin. Systemic availability of thiamine and riboflavin is reduced by the presence of Fuller's earth. Absorption of tetracycline from capsules is reduced by calcium phosphate due to complexation.

Most of these types of interactions were reported some time ago and are unlikely to occur in the current environment of rigorous testing of new dosage forms and formulations.

Coated tablets

Tablets may be formulated with coatings such as shellac, resin, or styrene-maleic acid copolymer. These coatings are insoluble in acid but dissolve readily at neutral or alkaline pH. Thus they are ideally suited to prevent drug release until the formulation has passed from the stomach into the small intestine. Preventing drug release in the stomach may protect drugs that are acid labile. It may also protect the patient from irritant substances like iron salts, diethylstilboestrol, and some anti-inflammatory agents.

Release, and subsequent systemic availability of drugs from these formulations is likely to be highly sensitive to stomach emptying patterns.

In vitro–in vivo correlations: The relationship between *in vitro* dissolution and *in vivo* bioavailability is of considerable interest today. The U.S. Food and Drug Administration (US FDA) has spearheaded a research program to examine these relationships with the objectives to gain a better understanding of their interdependence and to use the relationships as a means to predict *in vivo* performance from *in vitro* data. The cost savings of realization of this second objective would be significant. The main thrust of research in this area is based on differentiation of drugs or formulations in terms of solubility and membrane permeability (11).

Drugs or formulations can be considered in four groups: 1) high solubility and low permeability; 2) high solubility and high permeability; 3) low solubility and high permeability and 4) low solubility and low permeability. For drugs in group 3, dissolution is likely to be rate-limiting for absorption and *in vitro* dissolution data may be useful. For drugs in group 1, on the other hand, permeability is probably rate-limiting and *in vitro* data are less likely to be useful. For groups 2 and 4, the picture is less clear and *in vitro*–*in vivo* relationships would need to be determined experimentally.

Controlled release formulations

Appreciation of the advantages of controlled drug release, development of many novel controlled release systems, and also the interest of major pharmaceutical houses in protecting marketed drug products, have led to increased interest in this type of dosage form. Most controlled release products currently marketed include diuretic agents, cardiovascular and respiratory drugs, and compounds acting on the CNS. Little attention has been paid to antimicrobial agents.

Advantages of controlled drug release: Due to of their generally higher cost, controlled release dosage forms can be justified only if they offer therapeutic advantages, i.e., improved maintenance of therapeutic drug levels in the circulation, reduced dosing frequency, reduced fluctuation in circulating drug levels, increased convenience to the patient, reduced patient care time, less nighttime dosing, more uniform pharmacologic response, reduced GI irritation, and reduced side effects. The second of these, reduced dosing frequency, has often been claimed as a sufficient rationale for development of a controlled release dosage form, but has become unacceptable as a sole criterion. This is understandable given the current emphasis on cost containment in health care.

Disadvantages of controlled drug release: Potential disadvantages of controlled release dosage forms include the possibility of dose dumping, less facile dose adjustment, increased potential for hepatic first-pass metabolism, possible delay in onset of action, possibly lower system availability, and time of drug release limited to residence time of formulation in the optimum absorption region(s) of GI tract.

Dose dumping, or inadvertent rapid release of drug, is important for potent drugs that have a narrow therapeutic index. Good manufacturing practice (GMP) generally reduces the probability of this happening. Fine dose adjustment is often difficult with controlled release formulations. Controlled release tablets that use a granule matrix may be subdivided in order to reduce the dose, but repeat action tablets or osmotic pump devices lose their controlled release properties once the dosage form is fractured. Increased first-pass metabolism may occur with drugs that are cleared by the liver, but only if hepatic clearance is saturable following rapid absorption from conventional dosage forms. Reduced systemic availability is common with controlled release dosage form, availability generally being 80–85% of that from conventional formulations. Limited residence time in the GI tract is a potential disadvantage of oral controlled release products, and this distinguishes oral from other controlled release dosage forms (e.g., skin patches, which can provide slow release of drug over a prolonged period).

Drugs that are unsuitable for controlled release: Some drugs are unsuitable for controlled release formulations. Typical characteristics of such drugs include short biological half-life, long biological half-life, potent drug with narrow therapeutic index, large dose, poorly absorbed, low or slow dissolution, active absorption, time course of activity not the same as that of circulating drug levels, and extensive first-pass metabolism.

A controlled release form of a drug that has a short biological half-life, <2 h, or is administered in large doses may need to contain a prohibitively large amount of drug. Drugs with long biological half-lives (>8 h) are generally sufficiently sustained in the body from conventional doses, and prolonged release is unnecessary. Incorporating slowly dissolving compounds into a controlled release formulation is likely to be counterproductive since dissolution is rate-limiting anyway. Administering drugs like warfarin, whose pharmacologic effect is prolonged relative to its blood profile, offers no therapeutic advantage. Incorporating such compounds as some beta-lactam antibiotics, fluorouracil, and some amino acids, which appear to be absorbed predominantly from the proximal intestine, is likely to reduce their efficacy and

achieve little or no prolongation of effect. As stated earlier, if a drug undergoes saturable first-pass metabolism from conventional doses, its systemic availability may be decreased after controlled release.

Although the above arguments provide useful general rules, there are many exceptions. Nitroglycerin has a biological half-life of less than 0.5 h. It is generally considered to be poorly absorbed and is rapidly metabolized by the liver, with obvious first-pass implications. However, a large number of oral controlled nitroglycerin products are marketed. Low circulating levels of nitroglycerin obtained from these products appear to provide adequate prophylaxis against angina attacks, but not against acute angina episodes. Some established and more recently introduced controlled release dosage forms are given in Table 1 (12).

Absorption Enhancers

Although oral dosing is generally more convenient than other dosage routes, oral absorption of many drugs is poor. As molecules become larger, more complex, and generally more lipophilic in the quest for new or improved efficacy, their absorption tends to decline. To address this problem, absorption enhancers continue to be examined, so far with variable success. Some compounds that have been shown, largely in animal studies, to increase absorption of drugs are shown in Table 2 (13). Little or no information is available in humans for most of these compounds.

Nonsteroidal antiinflammatory agents (NSAIDs)

NSAIDs, in particular indomethacin, diclofenac, mepirazole, phenylbutazone, and salicylate, can promote absorption of other drugs, including insulin, ampicillin, cephalothin, cefoxitin, and cefmetazole. Most of these observations were made in the rat and frequently after rectal administration. Several mechanisms by which NSAIDs promote drug absorption have been postulated, but exact mechanisms are not known. As NSAIDs are often irritating to the GI mucosa, and this may well relate to their absorption enhancing ability, the feasibility of their use to promote drug absorption is uncertain.

Surfactants

In view of their solubilizing effects and also their potential to change membrane permeability, surfactants have been considered as absorption enhancers, again mostly in animals. Polyoxyethylene ethers have been shown to enhance gastric or rectal absorption of lincomycin, penicillin, cephalosporins, and fosfomycin in rats and

Table 1 Some oral controlled-release dosage forms

Category	Product	Active ingredient
Slow erosion with initial fast release dose	Tedral SA	Theophylline, ephedrine, phenobarbital
Erosion core only	Tenuate Dospan	Diethylpropion
Repeat action tablets	Chlor-trimeton repetabs	Pseudoephedrine, chlorpheniramine
Pellets in capsules	Combid spansule	Isopropamide, prochlorperazine
Pellets in tablets	Theo Dur	Theophylline
Leaching	Desbutal gradumet	Methamphetamine, pentobarbital
Ion exchange resin	Biphetamine	Amphetamine, Dextroamphetamine
Complexation	Rynata	Chlorpheniramine, phenylephrine, pyrilamine
Microencapsulation	Nitrospan	Nitroglycerin
Flotation–diffusion	Valrelease	Diazepam
Osmotic pump	Acutrim	Phenylpropanolamine
	ProcardiaXL	Nifedipine

(From Ref. 12.)

rabbits. In rats, colonic absorption of interferon- α is increased from 3 to 8% by polyoxyethylene esters of oleic acid and oleic acid glycerides.

Some studies have examined the effects of surfactants on intestinal absorption of insulin, with variable results. Both rectal and jejunal absorption of insulin was increased by anionic and cationic surfactants. However, in humans, oral polyoxyethylene-20-oleyl ether resulted in poor and variable insulin absorption (14).

Any enhancing effect of surfactants on drug absorption appears to be related to increased drug solubilization, modification of mucosal permeability, or reduction of resistance of the unstirred water layer at the GI membrane surface. In general, unionic surfactants have little effect on membrane structure but cationic surfactants have been associated with reversible cell loss and loss of goblet cells. These effects must limit consideration of surfactants as absorption promoters, particularly for long term treatment.

Table 2 Some types of oral drug absorption enhancers

Nonsteroidal antiInflammatory agents
Surfactants
Bile salts
Medium chain fatty acids
Mixed micelles
Liposomes
Azone
Cell permeation enhancers
Nanoparticles

(From Ref. 13.)

Bile salts

Bile contains conjugates of cholic acid and chenodeoxycholic acid, which emulsify dietary fat, facilitate lipolysis, and transport lipid molecules through the unstirred layer of the intestinal mucosa by micellar solubilization. The ability of bile salts to promote lipid absorption has prompted their investigation as absorption enhancers for drugs, with modest success. Studies in animals have demonstrated increased intestinal absorption of heparin and interferon- α . Absorption of insulin can be increased by bile salts, both in experimental animals and in humans. The effect on drug absorption appears to correlate with mucosal damage. This, together with possible cocarcinogenic and comutagenic properties of secondary bile salts, reduces the attractiveness of bile salts as absorption enhancers.

Medium-chain fatty acids and glycerides

The presence of medium chain fatty acids and glycerides in food products has stimulated interest in their potential utility as absorption enhancers. Some fatty acids and glycerides have been shown to increase drug absorption under a variety of conditions, almost always in animals and in most cases after rectal dosing. However, some studies have yielded positive results after oral dosing. Oral insulin bioavailability was increased to 9–13% relative to IM administration by a mixture of sodium dodecanoate and cetyl alcohol (15). Afiraxone absorption was enhanced by glyceryl-1-monooctanoate after oral, duodenal, and rectal administration to animals.

Despite the potential of these classes of compounds as absorption enhancers, they have been shown to have negative effects on mucosal membrane integrity. Additional research is needed to evaluate risks and benefits.

Mixed micelles

Mixed micelles consist of fatty acids solubilized by surfactants or bile salts. The effects of mixed micelles on drug absorption were reviewed by Muranishi et al. (16). Mixed micelles are effective absorption enhancers for compounds such as heparin, streptomycin, gentamycin, and insulin. The effect of mixed micelles on drug absorption tends to be greater at the distal region of the GI tract. The mechanism for increased absorption is not known. Some publications claim that they are safe to use. Others report a disordering effect on intestinal epithelial cells.

Liposomes

Liposomes consist of vesicles composed of bilayers or multilayers that contain phospholipids and cholesterol surrounding an aqueous compartment. Drug is entrapped within the liposome and is released from the liposome for absorption at the intestinal membrane surface. This dosage form received considerable attention during the 1970s and 1980s, and several animal studies demonstrated potential for absorption enhancement. However, lack of effect in other studies, and also stability problems, have resulted in reduced interest in liposomes as absorption enhancers.

Azone

Azone (1-Dodecylazacycloheptan-2-one) and related compounds have been studied as transdermal penetration and oral absorption enhancers. Although some efficacy has been shown, an emulsifying agent appears to be necessary for azone to penetrate the intestinal mucosal membrane in order to promote drug absorption. One study reported the absence of gross morphological damage after exposure of mucosa to azone (17) but additional information on the effect of azone on overall mucosa structure is not available.

Cell permeation enhancers

Although the objective of most absorption enhancers is to avoid direct interaction with the mucosal membrane, cell permeation enhancers use this as a means to increase drug absorption. One form of enhancer currently of interest consists of glycosylated molecules, or facial amphiphiles. It is claimed that these compounds temporarily increase membrane permeability. Molecules are designed to self-assemble in membranes to form transient pores that permit hydrophilic compounds to cross the membrane. This technology has considerable potential for absorption

enhancement. No adverse effects have been reported to date (18).

Nanoparticles

From known relationships between surface area and dissolution, it is reasonable to predict that ultrafine particles may increase the dissolution rate of relatively insoluble compounds. If these particles are then stabilized to avoid aggregation and agglomeration, and yet retain fluidity, then a useful drug product could be obtained.

This concept has found expression in a proprietary nanoparticle technology in which a drug is reduced to nanometer-size particles in the presence of stabilizers. Originally developed for IV computer imaging (19), this technology shows considerable promise to increase absorption of poorly water soluble compounds. As the nanoparticle system is purely "formulation" in nature, it is unlikely to affect GI mucosal integrity. Nanoparticles are sufficiently small that they can be used parenterally, apparently without ill effects. More is likely to be heard about this novel absorption enhancer technology.

CONCLUSIONS

The rate and extent of drug absorption into the systemic circulation are key factors that influence drug pharmacologic activity. Drugs may be administered by a variety of routes, each with its own advantages and disadvantages. The route of administration for a particular drug is dictated by the properties of the drug and the systemic activity profile required.

Increased knowledge of membrane structure and of transmembrane transport has improved understanding of the mechanisms of drug absorption and of ways in which this may be modulated.

Formulation continues to play a pivotal role in drug absorption. Many enhancer technologies have been examined, with varying success. However, some recent technologies based on formulation or membrane effects show considerable potential to increase absorption of orally administered compounds.

ABUSE OF DRUGS

Richard B. Seymour

David E. Smith

Haight Ashbury Free Clinics, San Francisco, California, U.S.A.

INTRODUCTION

Drug abuse may manifest at one of several different levels. Habituation involves a distinct and possibly harmful pattern of use. Drug abuse has been defined as a pattern of problem use that results in health consequences, social problems, or both. Drug addiction is a chronic disease of the brain that involves relapse, progressive development, and the potential for fatality if not treated. Addiction cannot be cured but can be brought into remission through a program of treatment, abstinence from all psychoactive substances, and supported recovery. In general, the drugs involved in abuse of drugs are within the grouping of “psychoactive” drugs. These are substances that have their primary effect on the brain and central nervous system (CNS) and include opioids, sedative–hypnotics, stimulants, and hallucinogens. Recent additions include performance-enhancing drugs, such as steroids, and combinations producing the effects of several drug groups.

LEVEL OF DRUG USE AND ABUSE

Inaba and Cohen (1) list six levels of drug use and abuse. These are: 1) abstinence, 2) experimentation, 3) social/recreational, 4) habituation, 5) drug abuse, and 6) addiction. These levels may not be progressive from one to the next, but will indicate in a progression context if the individual is developing a drug problem.

Abstinence

Abstinence means no use of psychoactive substances. However, in our culture, or for that matter in any culture, psychoactive substances are virtually impossible to avoid. Nearly all of us have experienced pain medication. Most soft drinks, tea, and, of course, coffee contain caffeine, a potent stimulant. Yet, individuals who partake of these will consider themselves abstinent and with few

exceptions this use is marginal to the point of not being worth consideration.

In terms of potential drug abuse or addiction, the nominally abstinent person is in little danger. Development of abuse requires the initial use of potent drugs. Addiction may involve a genetic vulnerability, but it also requires an environment that is conducive to initial use, and that will be lacking in the consistently abstinent individual, so long as he or she remains abstinent.

Drug Experimentation

Experimentation usually ensues when the individual becomes curious about a drug's effects or is influenced to try a drug by relatives, friends, coworkers or such cues as advertising and word of mouth. Many young people in the late 1950s and early 1960s tried marijuana when it was offered to them. Although all they may have heard about the drug in school, from parents, teachers, and other authority figures was highly negative regarding the drug, they were curious as to its effects and that curiosity overrode the warnings that they had received.

Experimentation, however, involves no pattern of use and usually minimal negative consequences. The individual may use on occasion as the occasion presents itself, but there is no drug-seeking behavior, and the consequences are minimal. There are exceptions, however, and these may include:

- Using a large amount, such as binge drinking in high school or college under peer pressure, that results in accident, injury, or illness
- An extreme physical reaction to a small amount of drug via an allergy or idiosyncratic reaction
- Aggravation or triggering of a pre-existing physical or mental condition
- Use during pregnancy
- Use resulting in legal problems such as an arrest for possession or loss of a job after failing a drug test or
- An addictive response from individuals with a very high susceptibility to compulsive use triggering immediate abuse or addiction.

Social or Recreational Use

With social or recreational use, the individual does seek out the drug or the situation in which the drug is used. However, there is no established pattern. Drug use is irregular, infrequent, and still has minimal impact on the individual's life. All of the possible exceptions listed in the preceding paragraph apply, with perhaps a greater chance given that drug-seeking behavior has become part of the pattern.

Drug Habituation

A definite pattern of use is apparent in habituation. This category includes the individual who needs a cup of coffee to kick-start the day, or a martini on arriving home to relax and end the day. So long as no real harm to others or oneself is taking place, this sort of consistent drug use can be considered habituation. This is the point, however, where use is apt to slide over into abuse. Habituation indicates that the user has lost some control over the drug, that use has become a habit, and with a nudge could become a bad habit.

Drug Abuse

Drug abuse can be transient: the product of stress, the acting out of social and cultural patterns, the response to overwhelming circumstances, or the need to perform. Examples may include taking a sedative to turn off and go to sleep after a hard day's work with a lot of mental but no physical exercise; doing cocaine or other stimulants to cope with a 24/7 lifestyle; having a weekly night out with the guys or staying over at the pub with coworkers on the way home; getting drunk to deal with a crisis one does not really want to face; or using steroids to bulk up for a professional sporting competition.

On the other hand, it can become chronic. Abuse behavior takes place on a regular basis, no matter what the circumstances. The behavior has become ingrained and part of the abuser's routine, such as the individual who must have a cigarette as soon as he or she wakes up in the morning, talks on the phone, and sits down to a meal, etc. As of yet, the problem is not addiction.

Drug Addiction

Drug addiction is a disease of the brain that is characterized by compulsion, loss of control, and continued use despite adverse consequences. Inaba and Cohen (1) define compulsion as "H spent most of their time either using, getting, or thinking about the drug" as the step between abuse and addiction. Seymour and Smith (2) consider "loss of control" the pivotal point. In the

recovering community, that is the point where the user turns from a cucumber into a pickle.

Addictive disease is characterized by compulsive use of one or more drugs and loss of control over that use. Here, we have the individual who goes out, swears he or she will have no more than two beers and instead gets very drunk, has a blackout, and cannot remember getting home. Continued use despite adverse consequences can include the businessman who continues to use cocaine even after losing family, possessions, and business, or the person who smokes two to three packs of cigarettes a day despite having lung cancer.

Addiction is progressive and can be fatal if not treated. It is incurable in that the addict cannot go back to noncompulsive, non-out-of-control use. In the recovering community, it is said that a cucumber can continue to be a cucumber, but once it becomes a pickle, it cannot go back to being a cucumber. Although incurable, the disease can, however, be brought into remission via abstinence from all psychoactive substances and a program of supported recovery.

Abstinence on its own is not enough for the addict. Addiction is a function of the lower brain and cannot be controlled by force of will. Craving will wear down the addict's resolve and in an attempt to resist can create a rigidity known in the field as "white-knuckle sobriety," in which the abstinent addict is clinging so hard that it is like the driver with such a grip on the wheel that his or her knuckles are bloodless. That is no way to drive a car or to maintain recovery from addiction. Recovery for the addict is a lifelong undertaking and requires help (3).

THE NATURE OF PSYCHOACTIVE DRUGS

Psychoactive drugs are substances that are chemically similar to chemicals that occur naturally in the human brain and act as neurotransmitters of information between brain cells. Because of the similarity, these chemicals are able to pass through the blood-brain barrier that exists to protect the brain from foreign materials. Once in the brain, all psychoactive drugs produce their effects by stimulating the release, inhibiting the release, blocking the reuptake, or imitating the brain's own neurotransmitters. Often, in such actions as producing pleasure, relief from pain or inhibitions, or anxiety, these drugs perform more rapidly and effectively than the endogenous substances. That is the primary appeal of these drugs. People use them because they work. They produce the desired results, at least for the short term.

THE PSYCHOACTIVE DRUG CATEGORIES

With a few notable exceptions, the bulk of psychoactive drugs that are abused by human beings fall into four general categories. These categories are: 1) opioid/analgesic drugs; 2) sedative–hypnotic drugs; 3) stimulant drugs; and 4) hallucinogenic drugs. There are drugs of abuse that either fall outside these basic categories, such as ether and other general anesthetics and steroids, or are considered to have attributes of more than one category, and these include the stimulant hallucinogens. Although the effects of psychoactive drugs may vary, they do have several things in common:

- Their principle action is in the brain and CNS, and they are therefore also referred to in the literature as “CNS” drugs.
- They are able to cross the blood–brain barrier that usually protects the brain from foreign substances because they resemble chemicals that are indigenous to the brain.
- They all act by stimulating, depressing, or imitating neurotransmitters that are native to the human brain and
- They all produce some form of disinhibition euphoria while they are active in the brain. It is this disinhibition euphoria that tends to be the most alluring general quality of psychoactive drugs.

Opioid Drugs

The narcotic/analgesic drugs have been used medically for pain relief and have been abused primarily for their ability to induce a state of euphoria and control pain. Historical accounts of opium extend to Assyrian depiction’s of goddesses with poppy pods growing out of their heads from around 4000 BC. Opium smoking became endemic in China in the 19th century after the British began exporting the drug from large holdings in India. In Britain, opium pills of 2–3 grains were easily available from apothecaries well into the 20th century. These and the tincture of opium, laudanum, are thought to have addicted many British writers and artists of the “romantic” and “pre-Raphaelite” periods. In the United States, opium and cocaine were often combined in patent medicine and tonics sold by traveling “snake-oil salesmen” in rural areas. The typical turn of the century opioid abuser was “a middle-aged, middle-class white woman with children.”

Natural opioids, that is, opioids extracted directly from opium include codeine—used for dental and other postoperative pain; laudanum, paregoric—a mild tincture of opium mixed with camphor and used primarily for

control of diarrhea; and morphine. Heroin is a partial synthetic that combines morphine and diacetyl acid. There are a number of synthetic opioids, including the highly powerful fentanyl (Sublimaze[®]), methadone—used in morphine and heroin addiction treatment, and such pain control mainstays as meperidine (Demerol[®]), hydromorphone (Dilaudid[®]), and oxycodone (Percodan[®]).

Medical use of opioids

Both natural and synthetic opioids are now, as they have been throughout medical history, the primary means of providing relief from pain and anticipatory anxiety. Along with analgesia, they induce a corresponding state of well-being or euphoria and at high doses somnolence, sometimes referred to as twilight sleep. They can also provide a sense of being immune to the effects of environmental and psychic distress, what street users refer to as “being in the wicker basket.” Opioid drugs can also be effective in controlling diarrhea and coughing.

How opioids work

The molecular structure of opioids is similar to that of certain neurotransmitters that occur naturally in the brain. Because of the similarities, these drugs are able to cross the blood–brain barrier and able to occupy receptor sites used by these neurotransmitters. The brain substances are called endorphins, which is short for endogenous morphines. The endorphins are what provide our natural pain control.

If we consider pain to be a signal that something is wrong, then endorphins are the internal means of mediating that signal. The subjective sequence is more or less as follows: Say you hit your thumb with a hammer. Intense pain. The brain receives the message, “Stop hitting yourself on the thumb with that hammer!” You jump around and yell a bit. It really hurts. After a while, however, you may still feel some surface pain from damaged thumb tissue, but the intense initial pain is gone. The endorphins that the pain released in the brain have attached to receptor sites that have disconnected the acute pain signal to your CNS, and even given you a little sense of euphoria.

Nonmedical use and abuse

Opioid drugs provide a vastly amplified version of what the internal pain management messengers provide. Beyond that, the use of opioid drugs gives the addict access to the reinforcement reward system, normally reserved to reward the performance of species-specific survival behaviors. That access provides the user with an experience that the brain equates with profoundly important events like eating, drinking, and sex. As a

consequence, opioid use becomes an acquired drive state that permeates all aspects of human life. This quality makes these drugs prime candidates for nonmedical use and abuse. Nonmedical use often involves self-medication and can be a result of medical misprescribing. Chronic pain sufferers, for example, may seek out street opioids to provide ongoing relief in situations in which they have been underprescribed for pain medication.

Whether iatrogenic in nature or developed on the street within a drug subculture, addiction to opioid drugs can occur with any drug in this category. Street users generally gravitate toward morphine and heroin, available through illicit dealers. Middle-class addicts and health professionals find prescription opioids more available to them. However, that can change over time and with changes in user status and drug availability.

Ingestion of opioids

Opioids may be taken orally in pill or liquid form, such as codeine or the many opioid-based prescription cough and diarrhea medications. They may be injected under the skin (skin popping), intramuscularly or intravenously. Injection has the added attraction of producing a “rush,” i.e., a relatively immediate drug reaction that has been described by users as being like a full body orgasm. Intravenous injection is said to produce the most intense rush. Given the expense and the frequent difficulty in obtaining opioids and the often low potency of street drugs, economy of delivery is often a consideration. Injection provides the least waste of drug in that the substance is introduced quickly into the bloodstream without previous evaporation or metabolism taking place. With higher potency heroin, however, smoking or “chasing the dragon” is often the choice. Smoking actually is the most rapid system for delivering opioids or any other drug to the brain, even faster than intravenous injection. Further, in light of AIDS, hepatitis C, and other illnesses that can be communicated by needle sharing, smoking is seen by users who can afford high-quality opioids as the safest use—and often seen by them as nonaddicting.

Physical dependence

Opioid users are subject to the classic symptoms of physical dependence. These are increasing tolerance and the onset of physical withdrawal symptoms. Tolerance involves needing more of the drug as time passes to achieve the same desired results. Physical withdrawal can initiate within hours of the last use and consists of a cluster of flu-like symptoms. Withdrawal is mediated by neural pathways separate from those involving the reward system, causing withdrawal events to be perceived as life-threatening, and subsequent physiological and

psychological reactions often lead to renewed opioid use. Withdrawal can be a tremendous force for continuing use, often at any cost (4).

Sedative–Hypnotic Drugs, Including Alcohol

Sedative–hypnotic drugs and anxiolytic drugs are CNS depressants that are used medically to reduce anxiety and/or induce sleep. They may also be used as anticonvulsants. Phenobarbital, for example, is often the maintenance drug of choice for seizure-prone individuals. In general, the sedative–hypnotic family of drugs includes alcohol, barbiturates, benzodiazepines, and such barbiturate-like drugs as chloral hydrate, glutethimide, meprobamate, and methaqualone.

The history of sedative–hypnotic drugs in medicine

The history of sedative–hypnotic drugs is one of attempts to find a drug or family of drugs that produces the desired effects without the risk of dependence and debilitating or life-threatening side effects and overdoses. In the 19th century, anxiety and insomnia were treated with opiates, bromide salts, chloral hydrate (developed in 1869), paraldehyde (developed in 1882), and alcohol. Each of these substances had its problems. The bromides could cause chronic bromide poisoning; many patients refused to take alcohol; and chloral hydrate and paraldehyde had objectionable taste and smell. As a result, the development of barbiturates was hailed as a major breakthrough.

Barbiturates

Barbiturates are all derived from barbituric acid, first obtained from uric acid and synthesized in Germany by Dr. Adolf van Baeyer in 1864. Conrad and Guthzeit synthesized the first barbiturate, 5,5-diethylbarbituric acid (barbital) in 1882. In 1903, Emile Fischer and Baron Josef von Mering introduced barbital into clinical medicine under the trade name Veronal[®]. Phenobarbital, which has remained the “model T” of barbiturates, first appeared on the market in 1912 as Luminal[®]. Unfortunately, intoxication with barbiturates is qualitatively similar to intoxication with alcohol and produced similar problems of abuse.

Benzodiazepines

A family of CNS depressants that has gained wide acceptance and use in the medical community is the benzodiazepines. These drugs, also called the minor tranquilizers, have been developed over the past 30 years, starting with chlordiazepoxide (Librium[®]), quickly followed by diazepam (Valium[®]). Since then, a variety

of benzodiazepines has been synthesized, including alprazolam (Xanax[®]) and triazolam (Halcion[®]). Benzodiazepines may differ in duration of effects and specific indications, but they are all cross-tolerant and chemically similar.

Major tranquilizers

Major tranquilizers like the phenothiazines, which include chlorpromazine (Thorazine[®]), are not usually subject to recreational-type abuse. Problems with these drugs most often involve misprescription or lack of understanding of their effects by health professionals. They are not considered to be addictive, and although a few deaths have been attributed to the ingestion of them at high doses, it is difficult to use them to commit suicide. The most notable problem with these drugs is the development of extrapyramidal symptoms, including facial and other abnormal movements of the head and neck, as well as such Parkinson syndrome-like symptoms as tremor at rest, rigidity, and shuffling walk.

Alcohol

Although its systemically administered medical uses have been limited to the treatment of methanol and ethylene glycol poisoning, alcohol is an excellent solvent and is used as a vehicle in many pharmaceutical formulations. It is also used topically as a disinfectant and to reduce fever through evaporation. Medieval alchemists considered it to be the “elixir of life,” a title that has survived in certain European fruit brandies called collectively *eau de vie*.

Although some cultures have expressly forbidden the use of alcohol (particularly some but not all Muslim cultures), most peoples have embraced this drug, giving themselves permission to use it ceremonially and recreationally, at least in moderate quantities. At the same time, alcoholism or alcohol addiction is considered to be a worldwide problem, and most cultures invoke sanctions against behavior related to alcohol overuse, such as drunk driving.

As a recreational substance, alcohol is second only to caffeine in worldwide use and second only to tobacco in health costs from abuse. In recent years, the American public has received a mixed message on alcohol's health benefits and deficits. Wine is said to help protect “moderate” drinkers from heart disease, but at the same time, alcoholism is responsible for more substance-related deaths than all other psychoactive drugs combined, with the exception of tobacco. Although there are few pharmacotherapies for alcoholism and alcohol abuse, a multimillion dollar project has been funded at the University of California at San Francisco by Gallo Wine

and the state of California to study alcohol neurochemistry and, if possible, to develop a cure for alcoholism. Remission from alcohol addiction was the aim of a fellowship developed in the mid-1930s, Alcoholics Anonymous, which today has a worldwide membership numbered in the millions.

Alcohol is usually imbibed in liquid forms such as beer, wine, brandy, and hard liquor, etc. The type of alcohol commonly consumed is known as “ethanol.” It is rapidly and efficiently absorbed into the bloodstream from the stomach, small intestine, and colon. Recent studies have suggested that women have a more efficient absorption than men. In the bloodstream, alcohol is distributed to all parts of the body, including the fetus(es) of pregnant women. Alcohol is metabolized in the liver and converted to acetaldehyde by the action of alcohol dehydrogenase (ADH) and other oxidizing agents at a relatively constant rate.

Adverse effects

The effects of sedative–hypnotic overdose or intoxication are similar for all drugs in this class. Ethanol acts as a classic sedative hypnotic drug, although the quality of sleep may be reduced by its ingestion. Intoxication works to decrease most mental and physical acuity, causing lapses in judgment, unsteady gait, slurred speech, slowed reactions, and mechanical difficulty. Blackouts, that is, continuing to function physically while being mentally disengaged, can occur as tissue dependence develops. Blackouts can be particularly dangerous in that users may forget how many pills they have taken and dose themselves into inadvertent overdoses. The degree of disinhibition euphoria can rapidly shift to dysphoria or even rage reactions with violent acting-out. In advanced stages, the intoxicated individual may pass out or, in extreme cases, lapse into a coma requiring emergency resuscitation. Acute intoxication to any sedative–hypnotic can be a life-threatening event.

Chronic abuse

The effects of chronic abuse can include memory impairment and chronic cognitive and psychomotor impairment. Tolerance develops to these drugs as the liver becomes more efficient in processing these drugs; however, the potential for a fatal overdose remains the same for these drugs. That means, as the sedative–hypnotic abuser needs and uses more of the drug, he or she comes closer and closer to a potential fatal overdose. Further, as a user gets older, age-dependent tolerance also occurs, in that the effect of a sedative–hypnotic on a 50-yr-old can be 5–10 times stronger than the same dose on a 20-yr-old.

Cross-tolerance and cross-dependence

Cross-tolerance means that tolerance to any sedative–hypnotic drug will extend to other drugs in the same class. Cross-dependency means that use of any drug in this class, or any opioid drug will enhance the effects and abusers may turn to other drugs in either category to either supplement their drugs of choice or stand in for them if they are not readily available.

Synergy and its dangers

Synergism can occur when more than one depressant drug, including alcohol, is used at the same time. In combination, that can cause a much greater reaction than the simple sum of effects. The liver tends to be choosy about what it metabolizes first. For example, diazepam is considered a relatively safe drug from the standpoint of being difficult to overdose on. However, if alcohol and diazepam (Valium) are taken together, the liver becomes busy metabolizing the alcohol, and the diazepam passes through to the brain at full strength. The result can be blackouts—resulting in even more use if the individual is medicating and forgets having already taken his or her medication, and extreme respiratory depression. These synergistic effects result in more than 4000 deaths a year and almost 50,000 emergency room visits for adverse multiple drug reactions (1).

How they work

Benzodiazepines, barbiturates, and alcohol act by stereospecifically binding to recently discovered receptors in the CNS. The effects of CNS-effective sedative–hypnotics have generally been linked to this complex, which also contains the receptor for γ -aminobutyric acid (GABA), the major inhibitory neurotransmitter in the brain and the chloride ion channel, through which chloride ions pass (5).

GABA receptors are the primary site of action for benzodiazepines in a highly complex process, but one that gives rise to the possibility of developing benzodiazepine agonists, antagonists, and inverse agonists. Benzodiazepine antagonists, such as RO15-1788 or flumazenil, may provide treatment options for both overdose and chronic abuse.

The Nature of Stimulant Drugs

Beyond the obvious of being stimulants rather than depressants, CNS stimulants have some basic differences from the two preceding groups of psychoactive substances. Although CNS stimulants can produce addiction, their users do not develop a steadily increasing tolerance.

Instead, as “presynaptic” drugs, they exhaust the brain’s own supply of stimulant neurotransmitters within the sympathetic system. This results in a binge pattern of use in which the user is forced to stop intense use periodically when the drugs no longer produce their desired effects so that the brain can replenish its supply of sympathetic transmitters.

The most common stimulant drugs are caffeine and nicotine, and their use is virtually worldwide. In recent years, the deleterious effects of nicotine have come under increasing scrutiny, particularly in the United States, where it has been recognized that tobacco is responsible for at least 400,000 deaths per year. At the same time that nicotine is being increasingly censured, caffeine is enjoying what seems to be an ever-increasing popularity. Perhaps this is because with increasing public health attention to the dangers of both tobacco and alcohol, it is the one remaining CNS drug that most people feel okay about using. Coffee shops have become the social centers of our society, and the market is increasingly dominated by chains that provide a wide variety of coffee products.

Caffeine

In general, coffee, tea, maté, Coca-Cola[®], and other sodas are so ubiquitous that people rarely think of them as drugs. Aside from individuals who are hypersensitive to caffeine, the controversy continues on whether caffeine itself is harmful or helpful to the people who use it. There is no doubt that caffeine is a CNS drug. It is well known that many individuals are physically dependent on its daily use and will exhibit withdrawal symptoms, including headache and disorientation, if their use is abruptly stopped. On the other hand, aside from the spiraling cost of cappuccinos, it may be hard to specify adverse consequences to the use of caffeine.

Writers such as Andrew Weil, M.D. (6), in his germinal book *The Natural Mind*, often contend that indigenous psychoactive substances used within cultural boundaries enhance rather than endanger the lives of their users. Plant stimulants, such as khat in Africa and the Near East and coca leaf-chewing in the South American highlands, are the most often cited as providing vitamins missing in the regional meager diets and needed stimulation for the hardscrabble existence of their users.

In teaching courses on drug abuse treatment to health professionals who may have had no personal experience with drug use and have a hard time understanding the compulsion involved, Richard Seymour asks how many are habitual coffee drinkers. Most hands usually go up. He then says, “Think about how you feel if you can’t get your first cup of coffee in the morning and then multiply that. That’s how the compulsive stimulant drug user feels.”

Other CNS stimulants

A drug similar in structure and effect to the amphetamines, methylphenidate (Ritalin[®]), and phenylpropanolamine, a stimulant vasoconstrictor that shows up in many cough and cold remedies, should also be mentioned. The most insidiously dangerous stimulant, nicotine as found in tobacco, is discussed briefly as well.

Cocaine

Cocaine is derived from the coca leaf, which has been chewed for its stimulant qualities by dwellers in the South American highlands since prehistoric times. When Spanish conquistadors first encountered the Inca Empire of Peru, coca leaves were a means of exchange controlled by the emperor himself. It is something of a miracle that coca leaf-chewing was not imported to Europe along with tobacco use at that time. And cocaine was not medically extracted from the leaf until 1860. Once the strong stimulant was isolated, however, it came into multiple use throughout Euro-American culture. Cocaine formed the original basis for coca-cola and could be found by itself or in combination with opium in a variety of quasimedical elixirs and tonics. Its use was recommended for the treatment of asthma, hay fever, fatigue, and at least a dozen other ailments. Sigmund Freud made frequent use of it, both personally and in his practice, and was involved in what may have been the first case of iatrogenic cocaine addiction. The most common use by serious abusers was by injection. Often cocaine was injected in a combination with morphine or heroin, called a “speedball.” By the early years of the 20th century, cocaine abuse had become serious enough in the United States for that drug to be included with heroin in the 1914 Harrison Narcotic Act.

Today, cocaine appears in several forms: coca leaf, liquid, powdered cocaine hydrochloride, purified freebase, and crack and can be chewed, insufflated, or snorted into the nose, injected (with or without opioids), or smoked.

Amphetamine and methamphetamine

Amphetamines are a 20th century development that first came into general medical use in the 1930s for a wide variety of medical conditions. During World War II, amphetamines were provided in large quantities to combat troops and bomber crews who had to stay awake and alert for long periods. After the war, production of these drugs remained high in most of the combatant countries, and they were readily prescribed by physicians for everything from depression to prefinals fatigue in college students. The first serious outbreaks of amphetamine abuse occurred in Japan, where stockpiles of the drug remained at the end of the

war, and in Sweden. Although some abuse had existed in the United States, the first postwar outbreak of stimulant abuse took the form of high-dose intravenous methamphetamine abuse between 1968 and 1969.

Stimulant drug pharmacology

Unlike opioid drugs, which work by imitating the indigenous morphines (endorphins) and attaching directly to the endorphin receptor sites, stimulant drugs produce their effects by acting as sympathomimetic agents and thereby stimulating the release of sympathetic neurotransmitters in the brain. The normal function of these sympathetic agents is to implement our “fight-or-flight” response by constricting blood vessels (vasoconstriction), increasing pulse rate and heart rate, increasing temperature (hyperthermia), and in general increasing alertness and response. These energy agents are also directly connected with the brain’s reward/pleasure center; thus, the satisfaction from using stimulants can be intense. One professional ball player who was introduced to cocaine at the height of his career said that the feeling from the drug was the same feeling he got when an entire stadium was on its feet shouting his name.

Nicotine

Tobacco, the primary source of nicotine, was used ceremonially in both pre- and post-Columbian America, imported to Europe where it was both embraced and reviled as a recreational drug, condemned by the court of James I of England, and today may be responsible for more than 400,000 deaths a year in the United States alone. Contrary to popular belief, although nicotine may help focus attention, it interferes with complex brain functions including access to long-term memory and the performing of multiple attention tasks.

Nicotine and the other ingredients in tobacco have been cited as causing a variety of fatal illnesses. A study by the Centers for Disease Control and Prevention (CDC) in 1991 listed the causes of death related to smoking with annual death toll as follows: (cardiovascular) heart disease, 150,000; stroke, 26,000; other, 24,000; (cancer) lung, 112,000; other, 31,000; (nonmalignant pulmonary disease) chronic obstructive pulmonary disease, 62,000; other, including pneumonia and influenza, 21,000; for a total of 426,000 fatalities a year directly attributable to tobacco. Further, the CDC points out that tobacco is also responsible for an annual death rate of 53,000 per year among nonsmokers affected by smoke in their immediate environment.

Pharmacologically, tolerance to tobacco develops quickly but once established, levels of smoking may remain about the same throughout one’s smoking career.

A withdrawal syndrome has been well established. Withdrawal symptoms may vary but can include craving for nicotine, irritability, frustration, anger, anxiety, depression, difficulty in concentrating, restlessness, and increased appetite. Although nicotine withdrawal is highly distressing and may continue for weeks, the compulsion to resume use may remain high for an extended period of time, and weight gain may be daunting, but it is not life threatening. However, detoxification can be an attenuated process of reversing neuronal adaptation to nicotine.

Although nicotine is also absorbed into the bloodstream through chewing and the use of snuff, inhaling cigarette smoke provides the most rapid brain access. Nicotine can also be absorbed through the skin, facilitating the use of skin patches. It is readily absorbed through the stomach, but first-pass digestion in the liver greatly decreases the amount reaching the brain from the stomach. Patients using nicotine gum are, therefore, now advised to mix the gum with saliva and lodge it between cheek and gum to facilitate absorption through the buccal mucosa.

Use of tobacco is bolstered by the positive reinforcement of producing euphoria and maintained by the negative of rapid-onset withdrawal symptoms as soon as nicotine levels decline below the brain's accustomed levels that are quickly relieved by the ingestion of nicotine.

The effects of amphetamine/methamphetamine

Stimulants promote the release of the brain's energy chemicals. On the short term, this can result in increased wakefulness and alertness, giving the occasional or situational user a performance edge. It was that edge that led science writers in the late 1940s to laud amphetamines as a wonder drug. Unfortunately, these drugs also deplete the available energy chemicals, induce a drug-based paranoia, and trigger intense cravings for more of the drug. Cocaine, in particular, blocks the reuptake of energy chemicals by the brain cells in which they are usually stored, creating a cerebral chain reaction until the chemicals are metabolized.

Prevention efforts

In keeping with their stimulant nature, cocaine and the stimulants produce a very rapid onset of abuse. Prevention efforts brought the slogan "Speed kills." Rock musician Frank Zappa filmed a TV commercial in which he said, "Kids, if you keep using speed you'll end up just like your parents."

The most effective amphetamine/methamphetamine prevention agent, however, proved to be the intravenous users themselves. These individuals tended to be walking, acting-out, negative advertisements of their drug. Anorexia

left them skeletal, whereas stimulant psychosis turned them into violent victims of delusional paranoia, a danger to themselves and others.

Although these efforts were effective to some extent, it became evident in the late 1960s that not only illicit manufacture of methamphetamine but the production and subsequent diversion of pharmaceutical psychoactive drugs were out of control, and the government and industry took steps to remedy the growing problem.

Hallucinogens

Although opioids and sedative-hypnotic drugs evolved primarily as medical substances for dealing with physical and psychic pain, and stimulants developed as recreational and performance-enhancing substances, hallucinogens had their role primarily within the realms of religion and magic. Throughout prehistory, history, and on into our own century, hallucinogenic substances have been used, often depending on the degree of sophistication of the culture in which they are being used, as a means of establishing contact with the spirit world, the realm of the gods, or the deeper reaches of the human subconscious. Shamans have used plant and mineral hallucinogens, often within the context of highly complex ritual to establish a point of contact between their people and their people's deities, or at least the supernatural forces that may affect their individual and collective lives.

Ethnobotanists have classified hundreds of plant hallucinogens, the majority of these originating in the rainforests of South America. In this article, however, the focus is on the five categories of hallucinogens classified by Goodman and Gilman (7):

1. Lysergic acid diethylamide (LSD)-like drugs, including mescaline, psilocybin, and psilocin;
2. Drugs that probably are LSD-like, such as DMA, DOM, and DMT;
3. Drugs that probably are LSD-like and have other properties, such as MDMA, MDA, and other amphetamine derivatives;
4. Drugs that probably are not LSD-like, such as 5-hydroxytryptophan; and
5. Drugs that are not LSD-like, such as scopolamine and δ -9-THC.

The history and nature of hallucinogens

The Goodman and Gilman classification obviously uses LSD as the base measure of hallucinogens. This LSD centrality most likely relates to the status of that drug as the most widely discussed and the most notorious of hallucinogens.

Although LSD was a relatively recent discovery, dating from 1943 when Dr. Albert Hofmann, a chemist at Sandoz Laboratories in Basel, Switzerland, accidentally ingested a small quantity of a substance he had first synthesized in 1938, its most active component, ergotomine, had a long history as a psychoactive agent. Occurring naturally as a rye-grain mold, ergotomine was featured in mystic potions in the classical world. In the Middle Ages, when its applied use had been forgotten, the hallucinogenic effects of ergotomine contamination in the bread supplies of entire communities was blamed on witchcraft and demonic possession.

Western scientific interest in hallucinogens was rekindled in the 19th century by poets and anthropologists observing and then participating in ceremonial rites involving psychoactive substances in a variety of cultures. Mescaline, the active ingredient in the peyote cactus used by religious sects in Mexico and the U.S. Southwest, was isolated in 1856 and by the turn of the century was available for research by the likes of Sigmund Freud, William James, and Havelock Ellis. It was, however, the discovery of what Dr. Hofmann considered the most powerful psychic drug (LSD) that induced tremendous scientific and popular interest in hallucinogen research.

With the advent of LSD availability, perception of these drugs underwent a process of evolutionary models. The first of these models was the psychotomimetic. This treated the drug experience as a form of psychosis, permitting researchers to study psychotic symptoms in nonpsychotic subjects. The psychotomimetic model was followed, although not necessarily superseded, by the hallucinogenic model, which treated LSD and mescaline as tools for studying the mechanisms of perception, and the therapeutic model, which involved the use of these drugs in the treatment of alcoholism, other forms of addiction, and mental health problems. Finally, there came the psychedelic model, which maintained that under proper conditions, the drug experience would be one of enlightening and productive consciousness expansion. It was with the psychedelic model that the use of LSD and other hallucinogens spread from the laboratory into the community.

Acute and chronic effects

The adverse effects of hallucinogens are generally divided between acute and chronic or long term. The acute effects, often referred to as “bad trips,” occur as direct negative results of hallucinogen ingestion and involve such elements as frightening images and thoughts, fear surrounding loss of control, and fear of losing one’s mind.

Acute effects: In 1967, David E. Smith, M.D., identified the adverse effects of hallucinogens as “largely psychological in nature,” and classified them as acute

toxicity, effects occurring during the use of the drug, or chronic after-effects (8). Although there have been some occurrences of physiological consequences, particularly with MDMA, these have been primarily of an idiosyncratic nature, although in most cases the adverse effects of these drugs still appear to be psychological in nature.

The acute toxic effects take many forms. Often individuals knowingly take a hallucinogenic drug and find themselves in a state of anxiety as the powerful hallucinogen begins to take effect. They were aware that they had taken a drug, but felt that they could not control its effects. This condition is similar to that of not being able to wake up from a threatening dream. Some users experience a bad trip and try to physically flee the situation, giving rise to potential physical danger. Others may become paranoid and suspicious of their companions or other individuals.

Not all acute toxicity is based on anxiety or loss of control. Some people taking hallucinogens display decided changes in cognition and demonstrate poor judgment. They may decide that they can fly, and jump out of a window. Some users are reported to have walked into the sea, feeling that they were “at one with the universe.” Such physical mishaps have been described within the acid culture as “being God, but tripping over the furniture.” Susceptibility to bad trips is not necessarily dose related but can depend on the experience, maturity and personality of the user, and “set and setting,” (i.e., the circumstances and the environment in which the trip takes place). Sometimes, the individual will complain of unpleasant symptoms while intoxicated and later speak in glowing terms of the experience. Negative psychological set and environmental setting are the most significant contributing factors to bad hallucinogenic trips (8).

Talkdowns of most acute toxicity reactions can be accomplished without medication or hospitalization. Paraprofessionals with psychedelic drug experience have been particularly effective at sites such as large rock concerts. In the talkdown approach, one should maintain a relaxed, conversational tone aimed at putting the individual at ease. Quick movements should be avoided. One should make the patient comfortable but not impede their freedom of movement. Let them walk around, stand, sit, or lie down. At times, such physical movement and activity may be enough to break the anxiety reaction. Gentle suggestion should be used to divert patients from any activity that seems to be adding to their agitation. Getting the individual’s mind off the frightening elements of a bad trip and onto positive elements is the key to the talkdown.

An understanding of the phases generally experienced in a hallucinogenic drug trip is most helpful, in treating acute reactions. After orally ingesting an average dose of

100–250 µg of LSD, the user experiences sympathomimetic, or stimulant responses, including elevated heart rate and respiration. Adverse reactions in this phase are primarily managed by reassurances that these are normal and expected effects of psychedelic drugs. This reassurance is usually sufficient to override a potentially frightening situation.

From the first to the sixth hour, visual imagery becomes vivid and may take on frightening content. The patient may have forgotten taking the drug, and given acute time distortion, may believe this effect will go on forever. Such fears can be dispelled by reminding the individual that these effects are drug-induced by suggesting alternative images and by distracting the individual from those images that are frightening.

In the later stages, philosophical insights and ideas predominate. Adverse experiences here are most frequently attributable to recurring unpleasant thoughts or feelings that can become overwhelming in their impact. The therapist can be most effective by being supportive and by suggesting new trains of thought.

The therapist's attitude toward hallucinogens and their use is very important. Empathy and self-confidence are essential. Anxiety and fear in the therapist will be perceived in an amplified manner by the client. Physical contact with the individual is often reassuring, but can be misinterpreted. Ideally, the therapist should rely on intuition rather than on preconceptions.

Wesson and Smith (9) noted that medication may be necessary and should be given either after the talkdown has failed or as a supplement to the talkdown process. During the first phase of intervention, oral administration of a sedative, such as 25 mg of chlorthalidopoxide (Librium) or 10 mg of diazepam (Valium), can have an important pharmacological and re-assuring effect.

During the second and third phases, a toxic psychosis or major break with reality may occur in which one can no longer communicate with the individual. If the individual begins acting in such a way as to be an immediate danger, antipsychotic drugs may be used. Only if the individual refuses oral medication and is out of behavioral control should antipsychotics be administered by injection. Haloperidol (Haldol) (2.0–4.0 mg administered intramuscularly every hour) is the current drug of choice. Any medication, however, should only be given by qualified personnel. If antipsychotic drugs are required, hospitalization is usually indicated. It has been found at the Haight Ashbury Free Clinics, however, that most bad acid trips can be handled on an outpatient basis by talkdown alone.

As soon as rapport and verbal contact are established, further medication is generally unnecessary. Occasionally, an individual fails to respond to the above regimen and

must be referred to an inpatient psychiatric facility. Such a decision must be weighed carefully, however, because transfer to a hospital itself may have an aggravating and threatening effect. Hospitalization should only be used as a last resort.

Chronic hallucinogenic drug aftereffects: These present situations wherein a condition that may be attributable to the ingestion of a toxic substance occurs or continues long after the metabolization of that substance. With the use of hallucinogens, four recognized chronic reactions have been reported: 1) prolonged psychotic reactions; 2) depression sufficiently severe so as to be life threatening; 3) flashbacks; and 4) exacerbation of pre-existing psychiatric illness. Recently, a fifth chronic reaction has been listed in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, posthallucinogen perceptual disorder (PHPD).

Some people who have taken many hallucinogenic drug trips, especially those who have had acute toxic reactions, show what appear to be serious long-term personality disruptions. These prolonged psychotic reactions have similarities to schizophrenic reactions and appear to occur most often in people with pre-existing psychological difficulties, such as primarily prepsychotic or psychotic personalities. Hallucinogenic drug-induced personality disorganization can be quite severe and prolonged. Appropriate treatment often requires antipsychotic medication and residential care in a mental health facility, followed by outpatient counseling.

At the Haight Ashbury Free Clinics, it has been noted that some of the clients self-medicated their hallucinogenic-precipitated psychotic episodes with amphetamines (10). Often, this self-medication with amphetamines resulted in the development of amphetamine abuse, followed by secondary heroin, barbiturate, or alcohol abuse patterns, to ameliorate the side effects of the amphetamines. Thus, in certain patients, chronic psychological problems induced by LSD and other hallucinogenic drugs led to complicated patterns of polydrug abuse that required additional treatment approaches (9).

Flashbacks: By far the most ubiquitous chronic reaction to hallucinogens is the flashback. Flashbacks are transient spontaneous occurrences of some aspect of the hallucinogenic drug effect after a period of normalcy that follows the original intoxication. This period of normalcy distinguishes flashbacks from prolonged psychotic reactions. Flashbacks may occur after a single ingestion of a psychedelic drug, but more commonly occur after multiple psychedelic drug ingestion.

Flashbacks are a symptom, not a specific disease entity. They may well have multiple causes, and many cases called flashbacks may have occurred although the

individual had never ingested a psychedelic drug. Some investigators have suggested that flashbacks may be attributable to a residue of the drug retained in the body and released into the brain at a later time. Although this is known to happen with phencyclidine (PCP) and drugs similar to it, there is no direct evidence of retention or prolonged storage of such psychedelics as LSD.

Individuals who have used psychedelic drugs several times a month have indicated that fleeting flashes of light and afterimage prolongation occurring in the periphery of vision commonly occur for days or weeks after ingestion. Active and chronic psychedelic drug users tend to accept these occurrences as part of the psychedelic experience, are unlikely to seek medical or psychiatric treatment, and frequently view them as "free trips." It is the inexperienced user and the individual who attaches a negative interpretation to these visual phenomena who are likely to be disturbed by them and seek medical or psychiatric help. Although emotional reactions to the flashback are generally contained within the period of the flashback itself, prolonged anxiety states or psychotic breaks have occurred after a frightening flashback. There is no record of flashback activity specifically attributable to hallucinogenic drug use occurring more than a year after the individual's last use of a psychedelic drug (10).

Chronic consequences of hallucinogen use: The long-term study of adverse hallucinogenic drug reactions has revealed the existence of low prevalence, but quite disabling chronic consequences of LSD use. Of particular concern is PHPD. With PHPD, individuals describe a persistent perceptual disorder that they describe as being like living in a bubble underwater. They also describe trails of light and images after moving their hands, and they often describe living in a purple haze. This perceptual disorder is aggravated by any psychoactive drug use, including alcohol and marijuana, and is distinguished from flashbacks, which are episodic rather than chronic phenomena. With PHPD, the individual often experiences anxiety, even panic, and becomes phobic and depressed. With PHPD sufferers, our experience has been that individuals do not have a disturbed psychiatric history before the onset of psychedelic drug use and that PHPD can occur even after a single dose.

With more severe, prolonged hallucinogen reactions, such as an LSD-precipitated schizophrenic reaction or severe depressive disorder, individuals almost always have a premorbid psychiatric history and require inpatient treatment. With the prolonged psychotic reactions, antipsychotic medication is required, and with the

prolonged depressive reactions, antidepressant medication is required. A major concern involves teenagers with depressive reactions to psychedelic drug use that may result in severe depression culminating in suicide.

With PHPD, drug-free recovery with supportive counseling is often adequate treatment, although recovery may take several months, and anti-anxiety medication may be needed to treat the secondary anxiety and panic disorder that develops when the individuals feel that they are irreversibly brain-damaged and will never see normally again.

Other concerns with hallucinogen abuse: There are many variations on the conditions addressed above, particularly with PCP, a mind-body disassociative drug that can act as a stimulant, a depressant, and a hallucinogen, depending on the dosage. These are discussed in another article on treatment and assessment. Suffice it to say, the etiology and pharmacology of hallucinogenic drugs is varied and involves a number of differing symptoms and sequelae.

ADVERSE DRUG REACTIONS

Therese I. Poirier

Robert L. Maher, Jr.

Duquesne University, Pittsburgh, Pennsylvania, U.S.A.

INTRODUCTION

Adverse drug reactions (ADRs) are types of adverse drug events (ADEs) (1). ADEs include ADRs, medication errors, and other drug-related problems. ADEs are the negative consequences of drug misadventures. Henri Manasse defined drug misadventure as the iatrogenic hazard that is an inherent risk when drug therapy is indicated. This chapter will focus on ADRs.

DEFINITIONS

The World Health Organization's (WHO) and Karch and Lasagna's definitions of an ADR are quite similar. An ADR is any response to a drug that is noxious and unintended, and occurs at doses used for prophylaxis, diagnosis, or therapy, excluding failure to accomplish the intended purpose (2). The Food and Drug Administration (FDA) focuses on ADRs that have unexpected reactions and/or those of more significant morbidity. These ADRs would include those where the patient outcome is death, life-threatening, hospitalization, disability, congenital anomaly, or required intervention to prevent permanent impairment or damage (3). The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) is concerned with the reporting of significant ADRs. Those that result in morbidity, require additional treatment, require an increased length of stay, temporarily or permanently cause disability, or cause death must be reported to the FDA (4). The American Society of Health-System Pharmacists (ASHP) defines significant ADRs as any unexpected, unintended, undesired, or excessive response to a drug that includes the following:

- Requires discontinuing the drug
- Requires changing the drug therapy
- Requires modifying the dose
- Necessitates admission to the hospital
- Prolongs stay in a health care facility
- Necessitates supportive treatment
- Significantly complicates diagnosis

- Negatively affects prognosis or results in temporary or permanent harm, disability, or death (5)

The ASHP definition does not include reactions due to drug withdrawal, drug abuse, poisoning, or drug complications.

Other terms that may be included as ADRs are side effects, drug intolerance, idiosyncratic reactions, toxic reactions, allergic reactions, or hypersensitivity reactions (6). *Side effects* are reactions that are unintended and unwanted but are known pharmacologic effects of the drug and occur with predictable frequency. *Drug intolerance* is a mild reaction to a drug that results in little or no change in patient management. *Idiosyncratic reaction* is an unexpected response that occurs with usual dose of a drug. *Toxic reaction* is a predictable response that results from greater than recommended drug dosages or drug concentration in the body. *Allergic or hypersensitivity reaction* is an unusual sensitivity to a drug of an immunologic nature.

CLASSIFICATION SYSTEMS

Four classification systems are used to describe ADRs (1, 7). ADRs can be classified according to the pharmacologic effect of the drug—Type A, B, C, and D reactions. Type A reactions are exaggerated but normal pharmacologic actions of a drug. They are predictable and dose dependent. Type B reactions are not predictable given the known pharmacologic action of a drug and are not dose related. Many of these Type B reactions are hypersensitivity or immune-based. These reactions can be further subdivided into type I (IgE-mediated reaction), II (IgG or IgM-mediated cytotoxic reaction), III (IgG-mediated immune complex reactions), and IV (cell-mediated immune reaction). Type C reactions are those due to long-term use of a drug. Type D reactions are delayed drug effects, such as due to carcinogenicity or teratogenicity.

ADRs can also be classified according to the dose relationship, i.e., dose-related and non-dose-related reactions. Another classification system is based on the causal relationship between the reaction and the drug. One of the

most widely used causality classifications is based on Naranjo's descriptions. These categories include definite (drug is likely the true cause), probable (drug is the apparent cause), possible (drug appears to be associated), and remote (drug is not likely to be the cause). The fourth classification system is based on degree of injury or severity of reaction. There are mild reactions (temporary discomfort and tolerable), moderate (significant discomfort), and severe (potentially life threatening or causing permanent disability or death).

INCIDENCE

The frequency of ADRs in the general population is unknown. However, the reported rates of new occurrences for ADRs are noted for selected patient populations. A meta-analysis of 39 prospective studies reported an overall incidence of serious ADRs in hospitalized patients of 6.7% and of fatal ADRs of 0.32% (8). The fatality rate makes ADRs the fourth to sixth leading cause of death in the United States. Another meta-analysis of 36 studies indicated that approximately 5% of hospital admissions are due to ADRs (9). The costs of ADRs are estimated to be \$1.56–\$4 billion in direct hospital costs per year in the United States (10).

FACTORS PREDISPOSING TO ADRS

Two major factors predispose to adverse drug reactions: the drug itself and patient factors. Factors related to the drug include its dose, dosage form and delivery system, and interactions between drugs. Patient-related factors include age, disease states, genetics, gender, nutrition, multidrug therapy use, and use of herbal therapies.

Drug-Related Factors

Dose

ADRs may be the result of ingestion of increased amounts of a drug. Dosing issues are especially likely with narrow therapeutic index drugs. Examples of these types of drugs include digoxin, anticoagulants, anticonvulsants, antiarrhythmics, antineoplastic agents, bronchodilators, sedatives, and hypnotics (11).

Dosage form and delivery system

Many of the ADRs related to the dosage form and delivery system are the result of local irritation or

hypersensitivity reactions (12). Local irritation to the gastrointestinal (GI) tract can occur with oral dosages. For example, toxicity resulting in mouth ulcerations is associated with antineoplastic drugs. In addition, the use of certain formulations, such as sustained release preparations, can increase esophageal injury if esophageal transit is delayed. For example, a controlled release wax matrix of potassium chloride has been associated with significant esophageal erosions. Factors identified to predispose to esophageal injury include large film-coated tablets, capsules, large sustained-release preparations, rapidly dissolving formulations, and ingestion of solid oral dosage forms before bed rest with very little water intake (12).

Localized tissue irritation can be seen from the intramuscular (IM) route. This is especially an issue when the formulation pH differs from the pH of the surrounding tissue or when precipitation of poorly soluble drugs occurs (12). Incorrect administration of IM injections is probably the most important factor that causes local adverse effects. Local skin irritation can also be seen with transdermal delivery systems due to the alcohols, nonionic surfactants, and adhesives.

Hypersensitivity reactions can occur due to the presence of contaminants or excipients in pharmaceutical dosage forms (e.g., outbreaks of eosinophilia-myalgia syndrome associated with oral tryptophan contaminants in various drugs) (12). Another example is the anaphylactoid reactions to the surfactant Cremaophor EL, which is used in paclitaxel (Taxol).

Direct toxicity effects related to use of preservatives also has been documented. For example, severe metabolic acidosis and death in infants was attributed to the presence of benzyl alcohol, a preservative used in bacterostatic normal saline that was used to flush catheters (12).

The use of specific intravenous (IV) delivery devices also can cause ADRs. For instance, use of plastic infusion sets for IV administration of nitroglycerin has resulted in subtherapeutic effects due to diffusion of the drug into the plastic tubes (12).

Formulation effects, such as bioavailability differences, can cause ADRs when patients are switched to generic products. For example, significant adverse effects have occurred with anticonvulsants and thyroid preparations (12).

Interactions between drugs

It has been estimated that 6.9% of ADRs are due to drug–drug interactions (6). The most likely reason for an adverse drug interaction is the pharmacokinetic changes that result in altered metabolism or excretion of drugs, or the

pharmacodynamic changes that result in synergistic or additive effects of drugs.

Patient-Related Factors

Age, disease states, genetics, gender, nutrition, multidrug therapy use, and herbal therapies use are patient-related factors that influence the likelihood of adverse drug reactions.

Age—geriatrics

Age-related alterations in pharmacokinetics and pharmacodynamics may affect the response of elderly patients to certain medications, and may increase the susceptibility for ADRs among elderly patients (13–15) (Table 1). The risk of ADRs among elderly patients is probably not due to age alone. ADRs may be related more to the degree of frailty and medical conditions of the patient (15). On average, older persons have five or more coexisting diseases that may increase the risk of adverse events. Polypharmacy seems to be more of a common problem among the elderly. The average elderly patient takes 4.5 chronic medications and fills 13 prescriptions yearly (15). Elderly patients appear to have a decline in homeostatic mechanisms. The imbalance of homeostatic mechanisms and the decline in function reserves may put a patient at greater risk for ADEs due to decreased tolerance of medications and the ability to handle stressful situations (16).

Age—pediatrics

The two factors responsible for increasing risks of ADRs in children are pharmacokinetic changes and dose delivery issues. Age-related differences in pharmacokinetics in children are documented (17). However, the data on both efficacy and safety are often limited or not studied at all in this population. Thus, it is unclear

whether an increased risk for ADRs exists in this group. However, there is a potential risk for increased ADRs if appropriate considerations are not taken into account in view of pharmacokinetic changes (18).

It is important to note that only one-fourth of the drugs approved by the FDA have indications specific for use in a pediatric population (17). Medications used in adults are often given to children without FDA safety and efficacy data. Compatibility and stability issues with dosage forms intended for adults that have been altered (e.g., dilution or reformulation) can increase risks for ADRs.

Information on pediatric age-related difference in neonates, children, and adolescents may aid in prevention of pediatric ADRs (18) (Table 2). Further studies of drug use in pediatrics are needed in order to prevent ADRs.

Concurrent diseases

Diseases such as hepatic or renal diseases can influence the incidence of ADRs by altering the pharmacokinetics of drugs, such as absorption, distribution, metabolism, or excretion (6).

Hepatic disease

Patients with liver disease have an increased susceptibility to certain drugs due to decreased hepatic clearance for drugs metabolized by the liver or due to enhanced sensitivity (6). For example, impaired hepatic metabolism can precipitate central nervous system (CNS) toxicity in patients on theophylline, phenytoin, or lidocaine; or ergot poisoning on ergotamine (19).

Increased sensitivity to drugs is also encountered in liver disease(19). The use of anticoagulants increases the risk of bleeding due to the reduced absorption of vitamin K or decreased production of vitamin K-dependent clotting factors. There is an enhanced risk for respiratory depression and hepatic encephalopathy due to morphine

Table 1 Geriatric age-related changes in pharmacokinetics

Pharmacokinetic phase	Pharmacokinetic parameters
Gastrointestinal absorption	Unchanged passive diffusion and no change in bioavailability for most drugs ↓ Active transport and ↑ bioavailability for some drugs ↓ First-pass effect and ↑ bioavailability
Distribution	↓ Volume of distribution and ↑ concentration of water soluble drugs ↑ Volume of distribution and ↑ half-life for fat soluble drugs ↑ or ↓ free fraction of highly plasma protein-bound drugs ↓ Clearance and ↑ half-life for some Phase I
Oxidation drugs	↓ Clearance and ↑ half-life of drugs with high extraction ratio
Renal excretion	↓ Clearance and ↑ half-life of renally eliminated drugs

↓ = Decreased; ↑ = Increased.

Table 2 Pediatric age-related risk factors and causes of ADRs

<i>Neonates:</i>
Placental transfer of drug before birth
Differing drug action
Altered pharmacokinetics
Increased percutaneous absorption
Decreased renal/hepatic function
Decreased plasma protein binding
Use of multiple drugs
Limited information on drug action in critically ill and premature neonates
<i>Children:</i>
Paradoxical effect of medications (excitability rather than sedation from antihistamines)
Excipients of liquid dosage forms
Sugar as sweeteners
Propylene glycol as solvent
Large volume intravenous solutions
Treatment of viral infections with antibiotics
Disruption of neurologic and somatic development
<i>Adolescents:</i>
Autonomy seeking
Use and misuse of devices (e.g., tampons)
Use and misuse of prescription and nonprescription medications
Poor compliance with instructions
Use of multiple medications
Recreational use of alcohol and illicit drugs
Effects of changing hormone levels on drugs

(From Ref. 7.)

or barbiturates in patients with severe liver disease. Vigorous use of diuretics can precipitate hepatic coma due to potassium loss in liver disease. There is an increased risk of hypoglycemia with sulphonylurea antidiabetic drugs due to decreased glycogenesis in liver disease.

Liver disease can also cause hypoalbuminemia due to decreased liver synthesis of albumin. For drugs that are extensively bound to albumin, such as phenytoin, an enhanced risk of drug toxicity could occur because of the increase in free drug concentration.

There are no useful methods to quantify the degree of liver disease that can assist in dosage adjustment. A practical approach involves checking patients for elevated prothrombin time, rising bilirubin levels, and/or falling albumin levels. In such instances, drugs that have an altered response in liver disease or cause hepatotoxicity need to be avoided.

Renal disease

Impaired renal function increases the incidence of ADRs for drugs that depend on the kidney for their elimination.

Unlike liver disease, use of pharmacokinetic dosing principles can minimize the risk for adverse effects.

Mechanisms responsible for enhanced ADRs in renal disease include delayed drug excretion, decreased protein binding due to hypoalbuminemia, and increased drug sensitivity (6). Delayed renal excretion is responsible for enhanced toxicity with drugs such as aminoglycosides, digoxin, vancomycin, chlorpropamide, H2-antagonists, allopurinol, lithium, insulin, and methotrexate (20). For some drugs, the accumulation of a toxic metabolite during renal failure is responsible for ADRs. This is the case with meperidine, where a toxic metabolite, normeperidine, accumulates in renal failure (20).

Patients with accumulation of uremic toxins have increased sensitivity to certain drugs. There may be an enhanced response to CNS depressants (such as barbiturates and benzodiazepines), hemorrhagic effects from aspirin or warfarin, and other bleeding effects from antibiotics that inhibit platelet aggregation, such as carbenicillin, ticarcillin, and piperacillin.

Other diseases

On theoretical grounds, other diseases associated with hypoalbuminemia could predispose patients to adverse reactions and to altered responses to drugs that are highly protein bound (21) (Table 3).

The presence of other diseases can influence the risk for ADRs. Many of these adverse effects are related to an extension of the pharmacologic effects of the drug in the presence of certain pathophysiology. Numerous examples are given in Table 4 (6).

Patients who have had a previous reaction to drugs are also more likely to experience an ADR (22). Patients with history of allergic diseases also have an increased risk due to a genetically related ability to form immunoglobulin E.

Genetic factors

Genetic factors account for some ADRs due to either altered pharmacokinetics or by altering tissue responsiveness. Altered metabolism of drugs occurs due to

Table 3 Conditions associated with hypoalbuminemia

Aging	Liver disease
Burns	Nephrotic syndrome
Cancer	Nutritional deficiency
Cardiac failure	Pregnancy
Protein-losing enteropathy	Renal failure
Inflammatory diseases	Sepsis
Injury	Stress
Immobilization	Surgery

Table 4 Influence of diseases on adverse drug reactions

Disease	Drug	Adverse reactions
Gastrointestinal		
Peptic ulcer	Aspirin, corticosteroids, nonsteroidal antiinflammatory drugs	Risk of bleeding or perforation of ulcer
Cardiovascular		
Heart failure	β -Blockers Lidocaine, theophylline	Aggravate or precipitate heart failure Enhanced toxicity—seizures
Myocardial ischemia	Tricyclic antidepressants Digoxin	Disturbances of cardiac rate, rhythm, and conduction Arrhythmias
Bradycardia	β -Blockers Quinidine	Cardiac standstill
Hypertension	Oral contraceptives, vasoconstrictors Phenothiazines, nitrates Tricyclic antidepressants	Increased blood pressure Decreased blood pressure
Hematologic		
Bleeding disorders—hemophilia	Aspirin	Increased risk of hemorrhage
Neurological disorders		
Myasthenia gravis	Aminoglycosides Quinidine, quinine	Aggravate muscle weakness Paralysis
Epilepsy	Phenothiazines Tricyclic antidepressants	Lower seizure threshold
Cerebrovascular	Ergotamine	Ischemic episodes
Rheumatic		
Systemic lupus	Drugs	Increased incidence of drug reactions in general
Hyperuricemia	Thiazide diuretics, furosemide	Gouty attack
Respiratory		
Asthma	β -Blockers	Acute bronchospasms
Respiratory insufficiency	Narcotic analgesics	Hypoventilation, respiratory arrest
Endocrine disorders		
Diabetes mellitus	Thiazide diuretics, furosemide, corticosteroids, oral contraceptives	Hyperglycemia; aggravates diabetic control
Hypothyroidism	Digoxin	Enhanced response
Hyperthyroidism	Oral anticoagulants Digoxin	Enhanced response Decreased response
Ocular		
Narrow-angle glaucoma	Anticholinergics	Glaucoma attack

differences in hydrolysis, acetylation, and hepatic oxidation of drugs. Altered pharmacodynamic reactions could be either an exaggerated response or a qualitative response. These types of reactions are unpredictable. Examples of altered drug response due to genetic factors are found in Table 5 (6).

Gender

A higher incidence of ADRs has been reported for women in comparison to men (6). One reason for this observation is that women take more drugs than men. Yet, no sex-linked differences in drug pharmacokinetics have been documented. Other reports have not supported a higher incidence of ADRs in women as compared to men. Thus, sex alone is unlikely to be a major determinant of ADRs.

Nutrition

Nutritional factors are also responsible for ADRs. These factors include the interaction of drugs and nutrients, and altered pharmacokinetics related to nutritional status.

One study reported a very low incidence (0.4%) of clinically significant drug–nutrient interactions in a teaching hospital (23). Three mechanisms postulated for drug–nutrient interactions are interference with drug absorption, alteration of drug excretion, and affecting drug activity. For example, the absorption of tetracycline is reduced by chelation with iron, calcium, and magnesium. Foods that acidify or alkalinize the urine can affect drug excretion. Foods that contain a large amount of vitamin K can inhibit the activity of warfarin. A listing of important drug–nutrient interactions is found in Table 6 (23). A review article on drug–food interactions in clinical practice is found in Ref. 24.

Drug–nutrient interactions may be more highly significant in renal failure patients. A review article of drug–nutrient interactions in renal failure has been published (25).

Nutritional status can affect drug pharmacokinetics. Malnutrition states can cause the following: 1) the liver and kidneys changes affect drug elimination; 2) GI system changes affect drug absorption; 3) changes in the heart affect blood flow; 4) hormone changes affect metabolic enzymes and drug binding proteins; 5) plasma, tissue proteins, and body composition changes affect protein binding and elimination; 6) mineral and electrolyte changes affect drug metabolism and protein binding; and 7) tissue changes affect uptake of drugs and drug–receptor interactions (26).

Multidrug use

According to several epidemiological studies, multiple drug use has a strong association in the causality of ADRs.

It has been suggested that the more medications used, the higher the risk for ADRs (27). Consistent drug regimen reviews by healthcare providers in order to reduce polypharmacy may decrease the risk of ADRs.

Herbal therapies use

The use of herbal therapies increased dramatically during the 1990s. Herbal therapy sales are estimated to be \$4 billion a year, with sales increasing at 20% per year since the early 1990s (28). Patients often mistakenly believe that since these products are natural, they do not possess the potential harm as in prescription medications. Since herbal medications are sold and marketed without stringent FDA approval and guidelines, limited evidence-based data on efficacy, adverse effects, and drug interactions exist. Recently, two review articles examined available data on ADRs for the most common herbal medications (28, 29). Many of these available reports fall short on documentation of temporal relationship with the specific ADR and the herbal drug.

For most conditions, herbal products are not a replacement for proven prescription or nonprescription drugs. Patients should be aware that health care practitioners cannot guarantee the safety and consistency of herbal products. Patients should start with the recommended effective doses and report any unusual side effects to their health care practitioner. Patients should always consult with their pharmacist for possible drug–herbal interactions. Side effects and possible drug interactions for the ten most commonly used herbals are listed in Table 7.

ADVERSE DRUG REACTION REPORTING SYSTEMS

The WHO, the FDA, the JCAHO, and the Health Care Financing Administration (HCFA) have all addressed and mandated the need for health care institutions to implement an ADE detection and reporting system. Detection systems are instrumental in postmarketing surveillance of ADRs. The JCAHO requires all accredited health care institutions to have an ongoing drug surveillance program (4). The goals of ADR detecting and reporting systems are to aid in postmarketing surveillance of FDA approved medications and to identify ways to decrease ADR risks. The main focus of all of these reporting systems is to aid in promoting improvements in the medication use process.

Table 5 Genetic factors and altered drug responses

Genetic mechanism	Drug(s)	Adverse drug response
Pharmacokinetic		
Low plasma pseudocholinesterase	Succinylcholine	Prolonged neuromuscular blockade leading to apnea
Slow acetylator	Isoniazid	Increased incidence of peripheral neuropathy; SLE-like syndrome; and more prone to phenytoin toxicity
	Hydralazine, procainamide	Increased incidence of SLE-like syndrome
	Phenelzine, sulfasalazine	More prone to side effects
Rapid acetylator	Isoniazid	More prone to hepatitis
Deficiency of epoxide hydrolase	Phenytoin, carbamazepine, phenobarbital	Life threatening hypersensitivity syndrome due to accumulation of toxic intermediates
Pharmacodynamic		
Glucose 6-phosphate dehydrogenase deficiency (G-6-PD)	Aspirin, BAL (dimercaprol), chloroquine, chloramphenicol, dapsone hydroxychloroquine, nalidixic acid, nitrofurantoin, primaquine, probenecid, quinine, quinidine, sulfonamides	Hemolytic anemia
Methemoglobin reductase deficiency	Acetaminophen, anesthetics, topical, benzocaine, chloroquine, dapsone, nitrites, primaquine, sulfonamides	Methemoglobinemia
Abnormality of calcium regulation	Anesthetics, general, (halothane), muscle relaxants (succinylcholine)	Malignant hyperpyrexia

Table 6 Important drug-nutrient interactions

Drug	Nutrient	Interaction
Phenytoin	Alcohol	Enhanced metabolism of phenytoin
	Enteral feedings	Decreased phenytoin absorption
Tetracycline	Dairy products	Impaired drug absorption
Theophylline	Caffeine	Potential for toxic effects
Warfarin	Foods high in vitamin K	Decreases anticoagulant response
Chlorpropamide, tolbutamide, tolazamide, acetohexamide, metronidazole	Alcohol	Disulfiram-like reaction
Trancylcypromide	Foods high in tyramine	Hypertensive crisis
Disulfiram	Alcohol	Nausea, blurred vision, chest pain, dizziness, fainting
Spirolactone	Foods high in potassium	Hyperkalemia

(Adapted from Ref. 23.)

ADR Screening Methods

The best methodology for screening for ADRs has not been determined. However, several screening methods have been proposed. In particular, the literature has highlighted five screening methods using clinical data (30–34). The five include screening for: 1) “tracer drugs,” e.g., antidotes such as vitamin K and diphenhydramine; 2) “narrow therapeutic range drugs,” e.g., follow-up of computer lab values for warfarin and digoxin; 3) change in medications, e.g., documentation of discontinued medications or decreased dose; 4) diagnosed ADRs documented in the medical record, e.g., chart review or reviewing ICD-9 CM (International Classification of Diseases, Ninth Revision, Clinical Modification) codes; and 5) ADR computer report tracking systems. Although each of these ADR screening methods has been described in detail, limited data are available on the productivity of these screens.

Systems for Pharmaco-epidemiologic Studies

Pharmacoepidemiology is used to detect ADRs (35, 36). Several types of systems use pharmacoepidemiologic methods. These include spontaneous reporting, studies of therapeutic classes, and studies of specific medical syndromes.

Spontaneous reporting

Spontaneous reporting is currently the major backbone for the detection of ADRs (37). It occurs in one of three ways:

1. Reporting to the FDA as part of clinical trials;

2. Reporting by practitioners to medical journals; or
3. Patients’ self-reporting to either manufacturers or the FDA (38).

Clinical trials in new drug development cannot detect all the possibilities for drug safety. Limitations in Phase III clinical trials include a relatively small sample size, short duration of the trial, restricted populations (e.g., geriatrics and pediatrics), uncomplicated patients, (e.g., limited disease states), and limited power for adverse drug reaction detection (30). Thus, the FDA relies heavily on spontaneous reporting of suspected ADRs (39). Spontaneous reporting is important in early market history of the drug to determine previously unidentified drug reactions. This has been particularly true in the last few years because of numerous new medications that have entered the market and now carry a black box warning. For example, Rezulin[®] and Trovan[®] are associated with hepatotoxicity and carry black box warnings.

Additional advantages of spontaneous reporting systems include the detection of extremely rare ADRs and ability to identify at-risk subgroups. In order to enhance the spontaneous reporting system approach, the FDA developed the MedWatch form. This form can be faxed to the agency (1-800-FDA-1078) or called in (1-800-FDA-1088) (40). The forms also can be obtained by the “MedWatch Online” internet-based website (<http://www.fda.gov/medwatch/>).

Limitations of FDA spontaneous reporting include both under-reporting and over-reporting.

An example of over-reporting occurs with recently approved drugs. This is partly due to enhanced publicity about these drugs.

Table 7 ADRs for the top ten herbal medicines

Herbal	Common use	Side effects and interactions
Echinacea	Treatment and prevention of upper respiratory infections, common cold	Rash, pruritis, dizziness, unclear long-term effects on the immune system.
St. John's wort	Mild to moderate depression	Gastrointestinal upset, photo-sensitivity. Mild serotonin syndrome with the following medications: paroxetine, trazodone, sertraline, and nefazodone. May decrease digoxin levels. May decrease cyclosporine serum concentrations. Combined oral contraceptives—breakthrough bleeding.
Ginkgo biloba	Dementia	Mild gastrointestinal distress, headache, may affect warfarin (increase INR). Interaction with aspirin (spontaneous hyphema)
Garlic	Hypertension, hypercholesterolemia	Gastrointestinal upset, gas, reflux, nausea, allergic reactions, and antiplatelet effects. May effect warfarin (increase INR)
Saw palmetto	Benign prostatic hyperplasia	Uncommon
Ginseng	General health promotion, sexual function, athletic ability, energy, fertility	High doses may cause diarrhea, hypertension, insomnia, nervousness, may affect warfarin (decreased INR)
Goldenseal	Upper respiratory infections, common cold	Diarrhea, hypertension, vasoconstriction
Aloe	Topical application for dermatitis, herpes, wound healing, and psoriasis, orally for constipation	May delay wound healing after topical application. Diarrhea, and hypokalemia with oral use
Siberian ginseng	Similar to ginseng	May raise digoxin levels. May affect warfarin (increased INR)
Valerian	Insomnia, anxiety	Fatigue, tremor, headache, paradoxical insomnia (not advised with other sedative-hypnotics)

Studies of therapeutic classes

Observational cohort or case control designs have been used to determine ADR relationships with specific therapeutic classes (36, 41). Medical claims data are often used in these studies and caution should be warranted due to lack of definite confirmation of drug exposure and the potential for confounding variables (38). However, these studies have been beneficial in determining risk of ADRs with specific classes (e.g., NSAIDs and the risk of peptic ulcer disease) (42).

Studies of specific medical syndromes

Observational cohort or case control designs can also be useful to study possible causality relationships of specific medical conditions or syndromes due to drug exposure (36, 41). These types of studies have been particularly useful in examining ADRs in a specific population, such as geriatric

or pediatric patients. These groups of patients are often excluded in Phase III trials. However, a disadvantage of these studies is that they also often use administrative data. These data can warrant risk of problems in determining causality due to potential confounding variables (38).

Assessing Adverse Drug Reactions

After detection of a possible ADE, causality assessment needs to be performed. It is important to be able to rank the likelihood of an ADR as unlikely, possible, probable, or definite. A major problem with determining causality is that confounding variables can contribute to the complexity of causality assessment (43). In order to determine causality, several important points of data are required. These include the nature of the adverse event, name of the putative drug, other potential causes, and the temporal relationship

Table 8 ADR Naranjo causality algorithm

	Yes	No	Do not know	Score
1. Are there previous conclusive reports on this reaction?	+1	0	0	
2. Did the adverse event appear after the suspected drug was administered?	+2	-1	0	
3. Did the adverse reaction improve when the drug was discontinued, or a specific antagonist was administered?	+1	0	0	
4. Did the adverse reaction reappear when the drug was readministered?	+2	-1	0	
5. Are there alternative causes (other than drug) that could on their own caused this reaction?	-1	+2	0	
6. Did the reaction reappear when a placebo was given?	-1	+1	0	
7. Was the drug detected in the blood (or other fluids) in concentrations known to be toxic?	+1	0	0	
8. Was the reaction more severe when the dose was increased, or less severe when the dose was decreased?	+1	0	0	
9. Did the patient have a similar reaction to the same or similar drugs in any previous exposure?	+1	0	0	
10. Was the adverse event confirmed by any objective evidence?	+1	0	0	
			Total score	

Probability category scores: Definite ≥ 9 ; Probable 5–8; Possible 1–4; Doubtful ≤ 0 .

between the drug and adverse event. Potential causes are obtained by examining the medical history, physical examination findings, and directed diagnostic tests.

Identification of causality can be performed simply by using a health care provider's clinical reasoning and judgment. The main disadvantage to this approach is a low inter-rater and intra-rater agreement for ADR causality (44, 45).

An ADR causality algorithm addresses the issue of inter-rater and intra-rater reliability with a series of clinical questions. For example, the Naranjo algorithm consists of a series of clinical questions that focus on temporal and dose–response relationships, consistency of the ADR with previous clinical reports or patient experiences, placebo response, drug dechallenge and rechallenge, toxic blood drug concentrations, alternative causes of the reaction, and whether the event was confirmed by objective evidence (44) (Table 8). Numerous health care institutions and the FDA use some type of causality algorithm to minimize disagreement among different evaluators and improve inter-rater and intra-rate agreement.

PREVENTING ADVERSE DRUG REACTIONS

ADRs are problematic in that they cause significant morbidity and mortality. Almost 95% of ADRs are Type A

(predictable) reactions, and thus with quality improvement measures, ADRs can be avoided and prevented (46). Knowledge of causative factors and an increase in patient education may help prevent ADRs. Improvements in the documentation of allergic reactions (e.g., via computer tracking), development of tools to enhance compliance, and application of tools to improve prescribing and administration of drugs are other preventative approaches to ADRs.

In 1994, the ASHP, the American Medical Association (AMA), and the American Nurses Association (ANA) generated the following system of recommendations to prevent ADRs in health care systems:

1. Health care systems should establish processes in which prescribers enter medication orders directly into computer systems.
2. Health care systems should evaluate the use of machine-readable coding (e.g., bar coding) in their medication use processes.
3. Health care systems should develop better systems for monitoring and reporting adverse drug events.
4. Health care systems should use unit dose medication distribution and pharmacy-based intravenous medication admixture systems.
5. Health care systems should assign pharmacists to work in patient care areas in direct collaboration with prescribers and those administering medications.

6. Health care systems should approach medication errors as system failures and seek system solutions in preventing them.
7. Health care systems should ensure that medication orders are routinely reviewed by the pharmacist before first doses and should ensure that prescribers, pharmacists, nurses, and other workers seek resolution whenever there is any question of safety with respect to medication use (47).

SUMMARY

Adverse drug reactions are of significant concern in the pharmaceutical technology arena. Various drug and patient factors that predispose to ADRs have been identified. Reporting systems used to screen and assess ADRs facilitate the understanding of risk factors and contribute to the development of systematic improvement in the prevention of ADRs.

ADVERTISING AND PROMOTION OF PRESCRIPTION AND OVER-THE-COUNTER DRUG PRODUCTS

Wayne L. Pines

Pharmaceutical Consultant, Washington, DC., U.S.A.

INTRODUCTION

Pharmaceutical companies aggressively market their products to assure that everyone who needs to know about them receives information in a timely way. The marketing of drugs has many aspects that are unique in the world of product marketing:

1. Pharmaceutical marketing is directed to a large extent at audiences who are not the ultimate users of the products (i.e., physicians, pharmacists, HMO managers).
2. Even in an age when mass media predominate, marketing to certain audiences such as physicians remains very personal.
3. The very fact that pharmaceutical companies market their products is controversial, as there are critics who believe that essential health care products should not be marketed.
4. The federal government dedicates significant resources and has established far-reaching and complicated rules to assure that pharmaceutical promotion is accurate and balanced.

A number of significant issues linger, such as how companies can communicate scientific information that is not within FDA-approved labeling; how to regulate the Internet; and the role of the brief summary. These and other issues make the field of advertising and promotion of pharmaceuticals dynamic and ever-changing.

BACKGROUND

The advertising and promotion of prescription drugs is inherently controversial. The drug industry maintains that such promotion provides an essential educational benefit and is needed to assure that the benefits of new drugs are made available to patients through their physician, pharmacist, or other health care provider. The industry stresses that promotion encompasses a variety of objectives beyond just selling more products. These

objectives include informing consumers about new and existing products that may be of value in improving their health; educating health care providers about new and existing products and how to use them; and providing information needed by those who finance or pay directly for medical products (1).

Further, the industry and advertising/promotion advocates contend that in the modern age there is an inherent need for pharmaceutical companies to communicate information about their research and new products. The public demands information about health care products; everyone wants to know about medical progress. Investment capital for new biotechnology companies is dependent on understanding the potential value and research progress of new products. Health care providers need to know, on a continuing basis, what kinds of advances are being made in their specialty.

When a new drug is introduced, pharmaceutical companies dedicate substantial resources to providing information to the health care provider through the sales force, and through advertising, direct mail, seminars, dinner meetings, presentations at medical meetings, exhibits, etc. In the 1990s promoting new drugs directly to the ultimate user, the patient, became common, and companies began to invest in magazine, newspaper, radio, television, and Internet promotional activities.

Critics of drug marketing say that such efforts are inappropriate ways to communicate information about prescription drugs. They say that pharmaceuticals are different from other heavily-promoted products in that they are necessary for health, can be harmful if misused or overused, and that they can mean the difference between life and death.

The critics say that advertising and promotion can endanger health by leading consumers to seek out and take certain prescription drugs that are inappropriate for their illness. They also say that promotional activities by drug companies are too expensive, adding to the price of prescription drugs and thereby denying access to those who cannot afford the drugs they need. They say that promotional activities are not needed, as medical information can best be conveyed through the medical

literature to physicians who then can determine what is best for their patients (2).

Finally, the critics have expressed concern about the accuracy and truthfulness of information issued by prescription drug manufacturers, fearing that such information will be biased because it comes from companies whose principal interest is in increasing the sales of its products.

The debate over the appropriateness of pharmaceutical promotion is one that will go on forever. The reality is that, at least in the United States, pharmaceutical promotion is an integral part of the process of health care delivery. It is heavily regulated by FDA to assure accuracy and balance. For the foreseeable future pharmaceutical companies will continue to use communications to capture the attention of various audiences.

EXTENT OF PHARMACEUTICAL ADVERTISING AND PROMOTION

There is no entirely accurate way to calculate how much is spent on advertising and promoting prescription drugs. The reason is that the term encompasses so many different activities. It includes, for example, traditional advertising in medical journals, visits to physicians and other health professionals by the company's sales force, dinner meetings, extensive exhibits at medical meetings, CME sponsored by drug companies, public relations programs, promotion directly to consumers using all media available, and outreach to professional and patient organizations.

Within drug companies the amount spent on promoting a particular product comes from many different budgets. Estimates on how much is spent in the U.S. on promoting prescription drugs range as high as \$13.9 billion. In 1999 the amount spent on direct-to-consumer television advertising alone was \$1.1 billion (3). Direct-to-consumer advertising of prescription drugs in consumer magazines, newspapers and on television has raised the visibility of prescription drug promotional activities.

Drug companies generally spend most on drug promotion when a new drug is being launched. Very often the promotional budget is cut dramatically, if not altogether, when a drug faces generic competition at the conclusion of its patent life.

REGULATORY HISTORY

FDA's role is to assure that all advertising and promotion of prescription drugs is accurate, provides full disclosure

of risks and is fairly balanced. There are two legal bases for FDA's jurisdiction over all advertising and promotional materials and programs issued by or sponsored (i.e. funded) by drug companies.

One legal basis of FDA jurisdiction is the 1962 Drug Amendments to the Food, Drug & Cosmetic (FD&C) Act. In 1962, the Congress added major amendments to the FD&C Act. The thalidomide incident—in which Americans were spared birth defects by a vigilant FDA that kept this potent teratogenic drug off the market—spurred enactment of the 1962 Amendments. But the Congress paid considerable attention in its legislative hearings to alleged advertising and promotion abuses by pharmaceutical companies.

Section 502(n) of the 1962 Drug Amendments dealt specifically with advertising. It assigned responsibility for prescription drug advertising to the FDA; previously, the jurisdiction had resided with the Federal Trade Commission (FTC). Section 502(n) was narrow in scope and vague in requirements. It said a prescription drug is misbranded

... unless the manufacturer, packer or distributor thereof includes in all advertisements and other descriptive printed matter issued or caused to be issued by the manufacturer, packer or distributor with respect to that drug a true statement of 1) the established name as defined in Section 502(e), printed prominently and in type at least half as large as that used for any trade or brand name thereof, 2) the formula showing quantitatively each ingredient of such drug to the extent required for labels under Section 502(e), and 3) such other information in brief summary relating to side effects, contraindications, and effectiveness as shall be required in regulations which shall be issued by the Secretary in accordance with the procedure specified in Section 701(e) of this Act: *Provided*, that a) except in extraordinary circumstances, no regulation issued under this paragraph shall require prior approval by the Secretary of the content of any advertisement, b) no advertisement of a prescription drug, published after the effective date of regulations issued under this paragraph applicable to advertisements of prescription drugs, shall...be subject to the provisions of sections 12 through 17 of the Federal Trade Commission Act, as amended... (4).

Basically, the law said that for a drug to not be misbranded, the generic name must be in the advertisement; the drug's formula must be included; and a "brief summary" of risks must accompany each advertisement. FDA was barred from requiring that advertising be approved in advance of use, a provision that addressed and

accommodated First Amendment (“free speech”) issues. In the 1960s FDA promulgated detailed regulations to implement Section 502(n).^a

The second legal base for FDA’s current regulatory authority over prescription drug advertising and promotion stems from the definition of “labeling” in Section 201(m) of the FD&C Act. This section defines “labeling” as printed or graphic materials accompanying a drug product. FDA regulations further define “labeling” to mean

brochures, booklets, mailing pieces, detailing pieces, file cards, bulletins, calendars, price lists, catalogs, house organs, letters, motion picture films, film strips, lantern slides, sound recordings, exhibits, literature and reprints and similar pieces of printed audio or visual matter descriptive of a drug and references published for use by medical practitioners, pharmacists or nurses, containing drug information supplied by the manufacturer, packer, or distributor and which are disseminated by or on behalf of its manufacturer, packer or distributor (5).

In effect, FDA combines Sections 502(n) and 201(m) and their implementing regulations to declare that any materials issued by or sponsored by a drug company about its prescription drugs are subject to regulation. In effect, promotional materials that are not deemed to be “advertising” are regulated as “labeling”. FDA has established virtually the same requirements for all promotional material, whether it comes under the definition of “advertising” or under the “labeling” definition (6).

Even though the FD&C Act as amended in 1962 did not envision FDA taking broad authority over all communications and marketing materials issued by drug companies, the drug industry has acquiesced to FDA’s increasingly broad definition of its authority. The industry has taken the view that just so long as FDA enforces the regulations even-handedly, the regulations help provide an underlying confidence in the accuracy of their materials. Further, the industry over the years has chosen not to challenge FDA’s assumption of authority in this area, choosing instead to wage its jurisdictional battles with FDA over other matters.

Over the years, a huge array of formal regulations, guidances, informal policies, and enforcement actions through warning letters has evolved from FDA. Combined, they establish a highly intricate system for regulating the advertising of prescription drugs.

The FDA has established authority over every word, footnote, picture and nuance of all promotional activities

issued by or sponsored by drug companies. That includes promotion to the consumer, press materials, detailing aids, continuing medical education, seminars, materials for managed care organizations. The agency has jurisdiction over oral statements made by a company representative to a physician.

Similar requirements exist for other medical products regulated by FDA. While pharmaceutical products are regulated by FDA’s Center for Drug Research and Evaluation (CDER), the comparable center that regulates biological products—the Center for Biologics Research and Evaluation (CBER)—basically applies the same standards. The regulation of the advertising of medical devices has its own legal basis, Section 502 (r) of the FD&C Act.

FDA regulations that apply to the promotion of medical products are spread out in several sections of the Code of Federal Regulations (Title 21). Among the applicable sections are Part 200 and, most particularly, Part 201 for pharmaceutical promotion; Part 510 for veterinary drugs; Part 601 for biological products; and Part 801 for medical devices.

FDA’s regulation of advertising and promotion was stepped up dramatically during the 1990s (7). The agency recognized that new forms of communications about prescription drugs had become more common, such as press releases, brochures for consumers, and cable television shows directed at physicians. The surge in promotional activity directed both at health professionals and consumers led FDA to increase significantly the resources dedicated to monitoring such activities and enforcing the regulations more aggressively, as well as the issuance of new policies to cover the new forms of communication. The increase in staff and enforcement occurred in every product category of FDA’s regulatory jurisdiction but was most pronounced in the pharmaceuticals area.

BASIC PRINCIPLES OF FDA REGULATION

The agency’s policies continue to evolve, in response to newer forms of communications and new needs of the medical marketplace. However, a few basic principles have been at the foundation of FDA’s regulatory approach (8).

All information in prescription drug advertising and promotional materials issued by or sponsored by drug companies must be truthful and not misleading. Only information consistent with FDA-approved labeling may be disseminated in promotional materials.

^a 21 C.F.R., Part 201 contains these regulations.

Any claims made about the product must be supported by scientific studies that have been reviewed by FDA or that are subject to FDA review. If a company wants to make, for example, a cost-effectiveness claim or a quality of life claim for a product, the claim must be substantiated by studies.

All benefits information must be fairly balanced with risk information. FDA defines “fair balance” as a “balanced presentation of benefits and risks.” This means that, in an advertisement, for example, to the extent that a particular benefit is described, the medical risks associated with that benefit also must be described. “Fair balance” also may mean that a product’s limitations must be delineated. “Fair balance” differs for each individual drug and communication technique. FDA requires that the presentation of all side effects and contraindications must have a prominence and readability that is reasonable, comparable to the presentation of benefits information.

All relevant material facts about the product must be disclosed. If an advertising or promotional piece omits to mention a material fact that would influence the prescribing, use or purchase of a product, then the piece would be rendered violative.

Whenever a product and its medical claim are promoted, there must be provision for the recipient of the information to obtain additional comprehensive information about the product. Advertising in print must be accompanied by the “brief summary” of risks. FDA permits print advertising directed at the consumer to be accompanied by a consumer-directed “brief summary,” which can be in the form of a Q&A. If a product is promoted directly to the consumer through a television commercial, then provision must be made to assure that the consumer can obtain substantial additional information needed to assess the benefits and risks of the product. Under an FDA guidance issued in August 1999, this requirement can be met through four mechanisms: an 800 number that the consumer can call to ask that the information be mailed or read; referral to an internet site; information in an advertisement in a current issue of a magazine; or materials that can be obtained from a health care provider (9).

The rules apply to any product-specific information issue or caused to be issued by a company, either directly or through any agent. Anyone with whom a prescription drug company has a financial relationship is, in effect, bound by the same communications rules as the company. A physician hired by a drug company to speak on its behalf is obligated to restrict promotional claims to approved labeling. The drug company is required to assure that this occurs.

SPECIFIC FDA ISSUES

FDA has expressed, through its guidances, policies and enforcement actions, particular concerns about certain issues.

Launch materials: These are defined as materials that are used to promote a product or a new indication when it first comes into the marketplace. FDA regards such materials as its highest review priority, because claims made in an introductory campaign for a new product or new indication establish certain expectations in the minds of health professionals or patients. The review of launch materials is FDA’s top advertising/promotion priority (10). While FDA by law cannot require the submission of such materials in advance of use, most companies submit launch materials before using them. FDA will not officially “approve” such materials, but will provide detailed comments on them. The failure by a company to change materials to address FDA’s comments creates a risk of an enforcement action.

Off-label promotion: This has become a highly controversial area involving FDA regulation. Promoting a marketed product for an unapproved use poses, in the view of the FDA, a significant potential threat to the public health. If health care providers and consumers are led to believe that a product is safe and effective for a use for which it is not approved, then adverse health consequences may occur. Further, if a product is approved for one use and then can be promoted for other uses, there is no incentive for companies to conduct the needed additional research.

FDA defines an unapproved use very simply: it is a use that is not in the FDA-approved labeling. It makes no difference to the FDA whether a use is widely practiced or is universally accepted by the medical community. The sole criterion for whether a claim can be promoted is whether it is included in the FDA-approved labeling. Thus, FDA can take action against a company when it promotes an indication not included in the approved labeling, even when medical scientists believe that a particular use is safe and effective. For example, in a 1993 consent decree signed by one company, FDA objected to its efforts to promote a drug for a use that was approved and widely accepted overseas, but not included in the product’s U.S. labeling (11).

FDA’s efforts to prohibit or restrict the provision of off-label information has been at the center of debate and controversy since the early 1990s. The Washington Legal Foundation, a conservative legal organization, filed a petition with FDA in October 1993 challenging the constitutionality of FDA’s rules regulating educational activities such as Continuing Medical Education (CME)

programs. The petition led to a case eventually wound up in the federal courts with rulings that, for most of the 1990s, left the issue unresolved (12).

While the Washington Legal Foundation case was wending its way through the courts, the Congress sought to resolve some of the central issues. Section 401 of the FDA Modernization Act of 1997 set forth a procedure for companies to secure FDA approval when they wanted to disseminate reprints and textbooks containing off-label to health care professionals. This procedure requires that the company be investigating the off-label use with the intention of seeking approval; that records be kept of who received the off-label information; that FDA clearance for the dissemination be sought; and that the information include a physician package insert, a bibliography and a disclaimer that the information is off-label (13).

As the debate over off-label information dissemination continues, FDA has other legal remedies to pursue if it believes that a company is issuing information that could lead to mis-prescribing or jeopardize the health of patients. FDA has said it can and will invoke a section of its regulations that prohibit the dissemination of information that is "false or misleading" (14).

The issue of off-label information is certain to remain controversial for some time, with the FDA seeking ways to restrict the dissemination of off-label information about prescription drugs and the legal community and industry seeking ways to provide such information to health professionals without stimulating enforcement actions.

Pre-approval promotion: FDA objects to the promotion of a product before approval. The agency's view was set forth in 1994 correspondence with a company, expressing the agency's interpretation of Section 312.7 of the regulations:

Prior to approval, promotional materials provided by the sponsor are often inaccurate with respect to the indications and risk information that ultimately appear in the approved product labeling. This inaccuracy occurs because the sponsor does not know what indications and other information the final product labeling will contain. Additionally, the sponsor's assessment of the drug may be overly optimistic, exaggerating efficacy while minimizing risk. Thus, the sponsor's biases may be incorporated into the promotional materials it provides prior to approval of final product labeling. Such promotional materials do not fulfill the needs of health care providers or benefits managers to obtain balanced, accurate information about new drugs, but instead disseminate misinformation and create potential risk and misuse (15).

Comparative claims: FDA requires that any comparative claim made by a company for its pharmaceutical product be substantiated with scientific evidence. Examples of comparative claims are "drug of choice," "unsurpassed," or "more effective." The supporting studies must be "head-to-head"—that is, they must be designed prospectively to compare the two products directly. FDA prohibits a claim of superiority based solely on data derived from two or more studies that are compared, even when those studies have similar protocols. Further, FDA requires that any comparative claim be clinically relevant to patients. And, if a comparative claim is made, it cannot be false or misleading and cannot leave out other measurements by which the company's product is inferior to its competitor.

Pharmacoeconomic and quality of life claims: Claims that a product is cost-effective, or that it will improve an individual's quality of life, may be made so long as there is proof. There is no firm standard for how such proof must be documented. In the case of pharmacoeconomic claims, the Food and Drug Administration Modernization Act of 1997 said that companies can provide cost-effectiveness information to managed care and other purchasing or reimbursing organizations, so long as the claims were based on "competent and reliable" information. This was intended to be a lesser standard than the usual one that FDA applies to claims of safety and effectiveness (which must be based on studies that are "adequate and well-controlled") (16). Quality of life claims, on the other hand, must be demonstrated in clinical studies.

Reminder advertisements: Companies often sponsor advertising that does not mention the indications for a product, but that is intended to "remind" readers or viewers of the name. Such advertising is called "reminder" advertising. Under an FDA regulation, such advertising may delineate the name (including the generic name), the ingredients, the dosage form and the name and address of the manufacturer, packager or distributor. The advertisement may not mention what the product is used for, and may make no safety or efficacy claim or any other representation about the product. Such advertising is exempt from the requirement for a "brief summary." "Reminder advertisements" may not be sponsored for prescription drugs for which there is a "boxed" warning in the FDA-approved labeling, or, in the case of older drugs, whose efficacy has not been reaffirmed by the FDA.

Press releases: FDA takes jurisdiction over the content of company-issued press releases by declaring them to be "labeling."^b As such, press releases must contain fair

^b FDA initially asserted jurisdiction over the content of product-specific press releases in 1983.

balance of risk information and must be accompanied by the full package insert. FDA also expects press releases to contain disclaimers that will help put the product into regulatory context (e.g., in a research announcement for a product not yet approved, the release should make clear that the product is not approved, or that an application is pending before FDA.) Press releases issued before product approval must avoid stating that the product has been shown to be safe and effective and should avoid any statements that might be construed as promotional, such as through use of words like “promising” or “break-through.”

Video news releases: Video news releases are 75- to 90-second electronic versions of press releases. They are regulated by FDA as promotional labeling, and therefore must contain balancing information. In addition, FDA expects the recipients of video news releases to have easy access to a physician package insert (17).

Publications intended for stockholders and investors: FDA regulates publications and other materials intended for stockholders and investors with the same rules as apply to materials for other audiences. However, the agency generally does not enforce the rules very aggressively when it is clear that the materials are for financial purposes rather than to promote a product’s use among physicians and patients. For example, FDA has never required annual reports issued to investors that mention ongoing research or newly approved products in a cursory way to include the labeling as an attachment.

Scientific exchange: FDA has adopted the view that “scientific exchange”—the well recognized need for scientists to communicate with each other about research findings—should be protected. When such “exchange” crosses over into “promotion”—and the line is hard to define—then FDA regulations are invoked.

Any scientific meeting whose content is fully under the control of a company and that is product-specific must meet all criteria for fair balance and full disclosure. This means that the materials and speeches must be within approved labeling.

A mechanism for drug companies to see that health professionals receive the latest results of medical research is for drug companies to sponsor CME programs. FDA has set forth detailed rules for how companies may influence and interact with legitimate CME programs about their products or product category. FDA permits such company-sponsored CME so long as the financial grant is provided to an accredited third party and the CME is conducted independently of the company. Companies that sponsor CME generally have standard contracts with providers that set forth the specific relationship that is intended to assure independence of the program, the presenters and the

derivative material such as monographs or publications (18).

Exhibits: Exhibits sponsored by drug companies at medical or other meetings are regulated by the FDA. The regulations require that all materials at the exhibit booth, including the headings in the booth itself, must be within approved labeling. There is provision within FDA’s regulations for scientific exchange outside of approved labeling so long as such discussions are not promotional, are conducted between health professionals, and so long as there is a clear distinction between approved indications and new research or off-label uses of a product. Companies often sponsor multiple booths at meetings, one for promotion of approved indications and the other for scientific exchange where new research is discussed.

Internet: The Internet has posed some unprecedented regulatory challenges. FDA has declined to issue a written guidance on Internet activities sponsored by drug companies, saying instead that it will apply the same standards to Internet advertising and promotional statements as it does to other means of communication (19). For the most part, corporate information that is not product-specific may be put on the Internet without regulation. So too, can information about approved products, so long as the information is consistent with labeling and provides ready and easy access to product labeling. The challenges arise with links to other Internet sites or with chat rooms, especially those that may contain off-label information, and how to manage information that emanates from overseas.

Requests for information: Companies may respond to requests for information from any external source. However, FDA differentiates between requests that are solicited by the company—that is, that the company has encouraged in any way—and those that are totally unsolicited.

If a request for information is solicited, then the company must stay within labeling in responding. If a request is totally unsolicited, then questions about off-label uses can be answered with information that is not restricted to approved label information. Companies can respond by providing research studies or other information. Generally, the medical affairs departments within companies handle responses to unsolicited requests for information. Companies usually keep records of such requests, and those records are subject to FDA inspection. If off-label information is sent to the requester, then the cover letter must make clear FDA does not approve the indication.

Accelerated approval drugs: These are drugs that receive priority attention by FDA and that, because they are for life-threatening conditions, are approved on the

basis of limited or surrogate marker data. FDAs regulations require that any advertising or promotional pieces for drugs approved through the accelerated process be approved prior to use. This requirement includes pieces used during the launch period as well as pieces used thereafter, for as long as the drug approval comes under the accelerated approval status (20).

Direct to consumer promotion: The promotion of pharmaceuticals directly to consumers began in the 1980s but came of age in the 1990s. In 1996, the amount spent on advertising prescription drugs to consumers exceeded the amount spent on advertising to physicians (though a company's promotional budget directed at physicians is still much higher than the consumer budget, since the highest spending is on sales representatives and direct promotion to physicians).

Print advertising directed at consumers must meet the same standard as print advertising directed at physicians. It must not only be accurate; it also must include a "fair balance" of benefits and risks, and it must include a "brief summary" of risks. FDA encourages companies to print "brief summary" information in consumer-friendly language.

Under a guidance issued in August 1999, FDA permits direct to consumer advertising on television. TV advertising must include a "major statement" of risk information. The TV commercial must also make provision for the consumer to obtain full labeling via the Internet or a toll-free number, and must also state that additional information is available from physicians, pharmacists or in an advertisement in a current publication (21).

FDA also permits advertising to consumers that does not mention the product name, but that identifies a disease condition and urges consumers to see their doctors. These are called "help-seeking" advertisements. However, FDA is sensitive to efforts to make implicit product claims that, while not mentioning the product by name, might be understood by a reasonable consumer as referring to a particular product.

FDA ENFORCEMENT

FDA monitors the promotional marketplace in a variety of ways. Staffers attend medical meetings, read consumer and medical publications, and watch TV. They are also asked to review materials in advance of use by drug companies. In addition, FDA learns of marketplace violations from competitor complaints. Finally, all advertising and promotional materials for prescription drugs must be submitted to FDA at the time of their first

use. Materials are submitted to the Division of Drug Marketing, Advertising and Communications (DDMAC) in CDER, or to the Advertising and Promotional Labeling Staff (APLS) in CBER. These are the staff that regulate the advertising and promotion of pharmaceuticals and biological products, respectively.

The growing prominence of advertising and promotion regulation during the 1990s made it necessary for pharmaceutical companies to dedicate more resources to the development and review of such materials. Virtually all companies have written policies and procedures for reviewing promotional materials and programs, including an internal review process. They also have dedicated regulatory staff that oversee the process. In addition, many companies regularly train staff on regulatory requirements. Periodic training has become a major focus for companies that want to be sure that everyone in the company, from top management to the sales force, is aware of the company's philosophy towards promotion and of FDA's rules.

The most common actions that FDA takes when it detects a violation are to send the offending company a letter (once known as a "Notice of Violation" or NOV, now known as an untitled letter) or a warning letter. An untitled letter identifies FDA's concern and seeks remedial action such as discontinuation of the promotional piece at issue.

Warning letters, which are sent far less frequently than untitled letters (the average is less than a dozen per year from DDMAC) are reserved for more serious situations. The issuance of a warning letter means that the agency has concluded that a legal violation has occurred and remedial action is needed. Usually the remedial action includes withdrawal of the violative materials and the company-wide dissemination of the warning letter. FDA may also seek a "Dear Health Professional" letter or other corrective measures such as mandatory training or pre-clearance of any new promotional materials for a period of time. In one instance, FDA required a company to produce corrective television commercials to address issues raised in a TV commercial that FDA found violative.

Untitled and warning letters provide 10 to 15 days for the company to respond and present a plan of action. Companies may appeal the FDA's finding and discuss the appropriateness of the remedial action, but FDA always retains the authority to seek more stringent action such as a consent decree. Warning letters are made public immediately upon issuance by FDA, and thus become a potential source of negative publicity. Untitled letters also are publicly available.

FDA has other enforcement options if it finds that a company has violated the advertising regulations. It can seek to negotiate a consent decree with a company if it feels that such a decree is needed to keep the company in

compliance. Three consent decrees involving advertising violations were signed in the 1990s. FDA may also seek a seizure, injunction or criminal action (misdemeanor or felony) against violative companies or products, but as a practical matter these more severe and time-consuming legal actions are unlikely. The most dramatic enforcement action taken by FDA in this area involved a fine of \$50 million against a company that allegedly overpromoted a product over a substantial period of years.^c

FTC REGULATION

The FDA has jurisdiction over prescription drug advertising and promotion, while the FTC has jurisdiction over the advertising and promotion of over-the-counter (OTC) medicines, as well as dietary supplements and medical devices (other than restricted devices as defined in the FD&C Act). FDA retains full jurisdiction over the labeling of all medical products, including OTC drugs and dietary supplements.

The FTC's authority over advertising, which predates FDAs, stems from Section 5 of the FTC Act, which gives the Commission authority to prevent companies from "using unfair methods of competition...and unfair or deceptive acts or practices in or affecting commerce." (FTC technically retains some legal jurisdiction over prescription drug advertising, but as a practical matter defers entirely to FDA, even for direct-to-consumer advertising.^d)

The FTC's organizational structure, regulatory approach and enforcement tools differ considerably from those of the FDA. This means that, in effect, there are different systems in place for regulating prescription drug advertising and OTC drug advertising. FDA and FTC work together in cases involving medical products. FTC does not have a medical staff, and any FTC action must be based on FDA-approved labeling. FDA and FTC operate under a Memorandum of Understanding dating back to 1971 and amended in 1992 that sets forth how the relationship between the two agencies will work.^e

FTC requires that a company have substantiation of any advertising or promotional claim. At any point, FTC may launch an investigation of an advertisement campaign for a

specific product, or, more commonly, for a category of products. An FTC investigation can originate from multiple sources—from any of the five commissioners or the semi-independent FTC staff. The commissioners must approve any enforcement actions recommended by the staff.

FTC procedures permit companies to engage in formal discussions with its staff before any matter is resolved. The usual resolution of an FTC investigation is the signing of a consent decree in which the company admits no wrongdoing but agrees never to do it again. FTC also has the authority, however, to seek a temporary restraining order or an injunction.

Over the years, FTC's enforcement has been directed to a large extent at advertising for fringe products, such as medical devices sold directly to the consumer that promise dramatic weight loss or some other body enhancement.

PRESCRIPTION DRUG MARKETING ACT

An important aspect of drug marketing is the provision of samples to physicians to provide to their patients. The Prescription Drug Marketing Act of 1987 is the statute that provides FDA with the authority to regulate drug marketing practices. It prohibits the diversion of prescription drug or biological products into illegitimate commercial channels. It also prohibits the sale of drug samples. The law provides that companies must obtain the signature of a physician for all drug samples. The law also requires record-keeping and careful storage of samples. Whenever a manufacturer discovers any diversion, it must report this to FDA.

Under the PDMA, physician requests for samples must be provided in writing. There must also be a signed receipt for the delivery of the samples. FDA regulations require drug companies to establish detailed, written procedures for product sampling programs, and to keep records of its sample distribution.

"ANTI-KICKBACK"

Another Federal law that applies to the marketing of medical products is the so-called "anti-kickback" law.^f This law, which dates from 1972, is not part of the FD&C Act; instead, it relates to Medicaid and Medicare statutes.

The "anti-kickback" statutes are intended to prevent overuse of and overcharging for medical products that are subject to government reimbursement either under

^c The three consent decrees were with Syntax, Kabi, and ICN. The \$50 million fine involved Genentech. See FDA Advertising and Promotion Manual for details.

^d FTC regulations are contained in 16 C.F.R. Part 251 and 255.

^e A copy of the Memorandum of Understanding, as amended, is in FDA Advertising and Promotion Manual.

^f 42 U.S.C., §1320a-7b.

Medicaid or Medicare (or other government-reimbursed health care programs). They prohibit any activity in which a medical products company may try to persuade, other than with sound therapeutic arguments, a physician or another health care provider or facility to use a particular product.

Specifically, the law prohibits a company from offering “any remuneration (including any kickback, bribe or rebate) directly or indirectly, overtly or covertly, in cash or in kind” to anyone to induce them to purchase a product or service for which reimbursement may be sought under Medicaid or Medicare. Regulations provide for “safe harbors.”

Many companies, in their internal training, include information about the “anti-kickback” statute. The Office of the Inspector General in the Department of Health and Human Services (HHS) enforces the “anti-kickback” law. HHS administers the Medicaid and Medicare programs. Any serious violations are referred for potential criminal prosecution to the Department of Justice; administrative sanctions also are possible.

LINGERING ISSUES

Many of the issues raised by FDA’s regulation of advertising and promotion remain subject to continued debate and lack resolution. These are issues that are important to resolve because until they are, there will be uncertainty in the marketplace and an uneven playing field from a regulatory standpoint.

Among the FDA’s policies that are most controversial are those that seek to restrict the dissemination by pharmaceutical companies of information from the scientific literature that is outside of FDA labeling. The issue revolves around the extent to which FDA can and should restrict such information, in an environment in which so much information is available from other sources such as the news media and the Internet.

Another issue is what are appropriate penalties for issuing violative materials. If a company issues information that is misleading, what are the appropriate remedies—e.g., letters to health professionals, corrective advertising? Further, and perhaps more importantly, what corrective measures are most effective? There has never been a study of the effectiveness of corrective measures imposed by FDA.

Still another issue is how FDA should regulate DTC advertising. How much information should the consumer receive about risks, and what is the best way to convey that information? A related issue is what role the “brief

summary” should play in the future. Does it still serve a useful purpose, or is it just an additional advertising expense for drug companies?

The Internet poses still another challenge to FDA regulation. FDA’s jurisdiction extends to promotional activities in the United States or directed at United States citizens. The Internet eliminates political borders and makes it impossible for FDA to regulate everything issued by drug companies on an international basis.

Issues like these are likely to remain for some time to come, as new means of communication evolve and as FDA, the Congress and the industry reevaluate the proper role and dimensions of regulation.

SUMMARY

The regulation of marketing practices by medical product companies—specifically their promotional programs—has become a highly specialized field within food and drug law. The rules are set forth in a variety of ways—in FDA regulations, in guidances and in enforcement actions, and are refined in public discussions by the regulators themselves.

The rules continue to evolve as new products are introduced and new means of communications become available, but basically a few principles apply. In essence, programs and materials must not only be truthful, they must also contain prominently appropriate risk information, and there may be no efforts by medical products manufacturers to persuade or induce health care providers to use products for uses not approved by FDA.

Alternative Medicines

Kristi L. Lenz

Medical University of South Carolina, Charleston, South Carolina, U.S.A.

INTRODUCTION

Although alternative medicine has the oldest healing practices, it is regaining popularity against a background of rapidly increasing technology in conventional medicine. For conventional health care practitioners, accepting the validity of alternative practices can be difficult, particularly because so little alternative medical training is provided at conventional medicine colleges and universities.

For pharmacy practitioners, herbal medicine presents a contradiction. Pharmacognosy, the study of natural product medicines, is a historical field of study in pharmacy. In addition, many conventional medicines are derived from herbs and other plants. However, in recent years, pharmacy has abandoned its “roots” in favor of clinical practice, and most pharmacists have little knowledge of herbals. No matter the level of pharmacist knowledge or bias on whether herbals can be helpful, the fact of the matter is that more patients are using them. This is sometimes at the risk of significant toxicity. All health care providers, but particularly pharmacists, need to develop a knowledge base of herbal medicines in order to best care for patients.

DEFINITIONS

Alternative Medicine

Often called “complementary and alternative medicine,” this group of medical practices has also been termed “unconventional,” “unorthodox,” “unproven,” and even “quackery.”^[1] Because these terms have significant negative connotations, terms such as “alternative medicine” are preferred. Alternative medicine is not one form of medicine, but rather a diverse group of health practices that are outside of what is considered usual or conventional by the medical establishment.^[2] Alternative medicine spans the range of practices, from home remedies to manufactured products, from patient self-treatment to care by a skilled practitioner, from efficacious to potentially dangerous. Specific definitions of more common alternative medicine practices used in the United States are listed in Table 1.^[1]

Herbal Medicine

Although alternative medicine encompasses a very broad range of practices (more than 150 in fact), the area of most interest to pharmacy practitioners is herbal medicine. Interestingly, there is no definition of “herb” in any federal legislation or in any Food and Drug Administration (FDA) regulation.^[3] Definitions vary considerably depending upon the source. For example, botanists define an herb as a plant whose stem dies back in winter (vs. trees or shrubs). On the contrary, pharmacognosists define herbs as the aerial parts of plants (vs. seeds or roots).^[3] The Herbal Trade Association, a group that has economic interests in this definition, defines an herb as a plant, plant part, or extract thereof used for flavor, fragrance, or medicinal purpose.^[3] In any case, herbal medicine implies the use of the *whole plant or plant part* as a remedy, rather than a single, active constituent derived from a plant.

SIGNIFICANCE OF HERBAL USE

Prevalence of Use

Phone surveys were done in 1990 and 1997 by Eisenberg et al. to determine the prevalence of alternative medicine use in the United States. Over 1500 participants were surveyed in 1990, as well as over 2000 in the follow-up survey in 1997. The percentage of participants surveyed who reported using at least one form of alternative medicine in the preceding 12 mo was 34% in 1990 and 42% in 1997.^[4,5] This is the oft-quoted “1 in 3 Americans use alternative medicine” statistic. Herbal medicine use rose from only 2.5% in 1990 to 12% in 1997, making it one of the fastest growing alternative medical practices used in the United States.^[4,5]

Demographics of Users

According to the surveys conducted by Eisenberg et al., alternative medicine users tend to be educated, younger to middle-aged, female, and have chronic medical conditions. They self-refer 90% of the time, meaning

**Table 1** Complementary and alternative medical practices

Practice	Definition
Acupuncture	Ancient Chinese technique that uses needles to pierce the skin
Aromatherapy	Taps into a grid of flowing energy ("qi") that controls organ function
Ayurveda	Uses botanical oils and essences to treat both physical and psychological disorders "Life knowledge"
Bioelectromagnetics	Ancient Indian practice that uses diet, exercise, yoga, meditation, herbs, and massage to treat imbalances in physical, emotional, and spiritual harmony
Chiropractic	Study of living organisms and their interaction with electromagnetic fields
Herbal medicine	Belief that magnetic fields penetrate the body and heal damaged tissues
Homeopathy	Practitioners use manipulation to treat disorders of the spine, joints, and muscles Plants that are made into pills or extracts to prevent and cure physical and psychological disorders "Like cures like"
Mindfulness meditation	Belief that very small doses of substances that would at high doses cause adverse effects can be used to cure those effects
Naturopathy	Preparations may be so dilute that the active ingredient no longer remains
Osteopathy	Belief that the mind can influence health and control physiologic responses
Reflexology	Relies on diet, fasting, massage, herbs, homeopathy, and other natural treatments
Therapeutic touch	Practitioners use manipulation to expedite recovery from disease or injury Practitioners also receive conventional medical training and prescribe drugs Spots on the foot are massaged to stimulate specific organs Caregiver moves hands inches above the patient's body to realign disturbed energy fields or remove "blockages"

(From Ref. 1.)

that their primary care practitioners are not involved in the decisions to pursue alternative therapies.^[4-7]

The use of alternative medicine varies with the patient population. For example, up to 80% of cancer patients report use of alternative medicine vs. one-third in the general population. Surveys also find that two-thirds use herbal medicine.^[7-10] Interestingly, cancer patients do not abandon conventional therapies when using alternative medicine, with close to 90% using both conventional and alternative medicines together.^[4,6,9] Particularly with herbal medicine use, this creates the potential for conventional drug interactions. In fact, in Eisenberg's^[5] 1997 survey, 20% of participants admitted to using conventional prescription medications with herbal supplements. Because less than 10% of herbal medicine users are under the care of an herbalist, pharmacists are often the only health care providers who can help to avoid potentially dangerous adverse effects and interactions.^[10] Similar to cancer patients, a large proportion (45%) of AIDS patients also report alternative medicine use.^[11] Of those patients, two-thirds use herbal supplements, and most use alternative practices with their conventional HIV treatments.^[11]

Reasons given by patients as to why alternative medicine is used include the following: the perception that conventional therapies are ineffective and/or toxic; frustration when no effective conventional therapy exists; the desire to take a more active role in their own care;

distrust of conventional practitioners; and the belief that alternative practitioners focus on the whole patient.^[6,10] Although most patients still use conventional medical practices with alternative medicine, only one-third tell their conventional practitioner that they are doing so.^[4,5,8] This again means that the pharmacist may be the only conventional health care practitioner who is aware of both patients' conventional and alternative medicine use.

Cost

It is estimated that over \$20 billion are spent each year on visits to alternative practitioners.^[5] Sixty percent of patients pay all of these costs out-of-pocket, with only 20% of health maintenance organizations (HMOs) and third-party payers supplementing at least some of these health care costs.^[5] It is also estimated that \$1-5 billion are spent on herbal supplements per year, and interestingly, less than 5% of patients who use herbals report that they bought those products in a pharmacy.^[5]

What Pharmacists Know

Given the recent rise in herbal supplement use and the potential dangers of misuse, one would expect that the pharmacy profession would be prepared to deal with public's need for reliable information on herbs.

Unfortunately, this is generally not the case. A 1998 survey done by the University of Mississippi found that only 2% of pharmacists felt confident in their herbal medicine knowledge.^[12] Another survey in 1998 performed in North Carolina and Virginia included a 15-point test on five of the most common herbal supplements.^[13] Of the 164 participants, 68% worked in a community setting and 74% sold herbals. However, the mean score on the 15-point test was only 6.3, indicating that pharmacists have inadequate knowledge with which to advise patients taking herbals.^[13]

One would also hope that Colleges of Pharmacy would have increased the education they give to pharmacy students on herbal medicine, to prepare them better for the needs of consumers. This has also been quite slow to change. There is very little detailed literature in this area; however, a 1997 survey was done and asked Colleges about alternative medicine courses in the curricula. Although three-fourths responded that they taught about alternative medicine, only one-third of the courses were required, and less than 40% of content taught was about herbals.^[12] Comparison of this statistic to a survey of breast cancer patients found that 71% of herbal users thought that herbals were “perfectly safe,” a fact known to be untrue.^[10] Pharmacists will not be able to help patients avoid harmful effects from herbals unless they are educated about uses, toxicities, and potential herb–drug interactions.

REGULATION AND OVERSIGHT

National Center for Complementary and Alternative Medicine

The federal government has had some insight into the need for a federal office to oversee dissemination of information on alternative medicine. Previously known as the Office of Alternative Medicine (established in 1992), the National Center for Complementary and Alternative Medicine (NCCAM) was established in 1998 as part of the National Institutes of Health.^[1,2] The mission of NCCAM is to “give the public reliable information on the safety and effectiveness of complementary and alternative medicine,” with an emphasis on clinical trial sponsorship.^[2] The budget of the NCCAM has grown from \$2 million in 1992 to almost \$70 million in 2000, and almost half the budget is mandated to fund peer-reviewed grants.^[2] The NCCAM also helps to disseminate information to the public, sponsors literature evaluations, and acts as an international liaison for alternative medicine. The NCCAM actually divides alternative medicine into seven broad categories:

1) alternative systems of medical practice (such as ayurveda and Chinese medicine); 2) bioelectromagnetics; 3) diet and nutrition (such as macrobiotics); 4) herbal medicine; 5) manual healing methods (such as chiropractic and therapeutic touch); 6) mind/body techniques (such as yoga and meditation); and 7) pharmacological and biological treatments (such as shark cartilage).^[2] More specific information about NCCAM may be found at the website: <http://nccam.nih.gov/>.

Dietary Supplement Health and Education Act

One would assume that the federal government would also take a significant role in regulating substances (e.g., herbal therapies) that have the potential to cause significant harm. Although the FDA does want to hold many herbs to a higher standard, political pressure has led to the passage of legislation that makes herbal supplements more widely available with less oversight. This legislation is the Dietary Supplement Health and Education Act (DSHEA).

Prior to DSHEA, herbs were inconsistently regulated as drugs, foods, and/or food additives. Several events led to the passage of DSHEA. In 1990, 258 ingredients in over-the-counter drug products were banned for sale by the FDA due to inadequate efficacy data. Eighty-five of these ingredients were of herbal origin. Manufacturers responded by either pulling the products from the market or, more importantly, selling the products as “dietary” supplements.^[14] This caught the attention of the FDA, and in 1993, the then Commissioner David Kessler publicly proposed that herbal supplements be held to the same standards as drugs, that is, be proven safe and effective or be removed from the market. These comments led to much public concern about continued availability of herbals, and many letters were written to members of Congress. The political pressure was great enough that in 1994, DSHEA was passed.

The DSHEA was a bipartisan bill cosponsored by Orrin Hatch of Utah and Tom Harkin of Iowa. First, it broadened the definition of a “dietary supplement” to include any product designed to supplement the diet that contained one or more of the following: a vitamin, mineral, herb, botanical, amino acid, or any metabolic constituent or extract thereof. To be removed from the market, supplements must be proven unsafe by the FDA. This is in contrast to drugs, where the burden of proof (both safety and efficacy) is on the manufacturer. Supplements must contain the labeling “Not evaluated by the FDA. This product is not intended to diagnose, treat, cure, or prevent disease.” They must also be labeled either “dietary supplement” or “herbal supplement,” as well as have the common name, Latin binomial, quantity, and plant

part used on the label. Products may be sold as dietary supplements as long as no health or therapeutic claims are made. So, structure/function claims are permitted, and the label may state things such as “elevates mood” or “maintains cardiovascular health.” Disease claims, however, are prohibited. For example, supplement labels may not state “treats depression” or “lowers cholesterol.”^[3,14]

Limitations of Regulations

There are several limitations that lead to potential for patient harm with the current regulation of herbals under DSHEA. First, botanical nomenclature is not standardized. Common names for herbals may vary depending on the region of the country. A single herb may have more than a dozen common names (e.g., echinacea), or one common herbal name may refer to several different species (e.g., yellowroot and snakeroot).^[14] To avoid confusion, the American Herbal Products Association (AHPA) has published *Herbs of Commerce*, a text of more than 500 herbs with the preferred common name, Latin binomial, and appropriate synonyms.

Second, good manufacturing practices (GMPs) of herbal supplement manufacturers are not regulated by the FDA. This means that there is no guarantee that what is on the label of the supplement is actually what is in the bottle. An example of this is a study published by Gurley et al.^[15] examining the ephedra alkaloid content of 20 herbal weight-loss supplements. Ten of the 20 supplements assayed (50%) had more than a 20% discrepancy between the actual ephedra content and the labeling. Four products also had significant lot-to-lot variation, up to 1000% of labeled ephedra content in one. Interestingly, one product contained no ephedra alkaloids at all.^[15]

Third, safety assurance is the responsibility of the FDA, not the manufacturer. This means that the FDA must accumulate a significant amount of proof that something is unsafe before pulling it from the market. In addition, to help professionals, the AHPA has published *The Botanical Safety Handbook* that summarizes safety data of more than 600 herbs. However, there is no guarantee that any particular manufactured product is safe. An example is a recent recall of PC-SPES supplements by the FDA.^[16] The PC-SPES is a combination of eight herbs marketed as a treatment for prostate cancer. It is known to have estrogenic activity, which is presumably how it affects prostate cancer.^[17] However, laboratory analysis performed at the California Department of Health found that the recalled products were contaminated with warfarin.^[16] The implications of this are that even if PC-SPES is thought to be safe, any given product could contain other potentially harmful substances.

Finally, efficacy of herbal supplements is difficult to establish. Many reported uses for herbs are hundreds of years old and anecdotal in nature. Because most herbal supplements cannot be patented, large pharmaceutical firms are reluctant to spend the money that is necessary to conduct randomized, placebo-controlled trials. To overcome this problem, in 1978, the German government established Commission E to evaluate the safety and efficacy of herbs. To date, more than 300 have been evaluated, and the monographs were translated into English in 1998. Unfortunately, most consumers do not have access to these monographs, and the language in DSHEA simply adds to the potential for patient harm, with structure/function claims leading to vague and potentially dangerous messages to consumers. For example, echinacea is often marketed as a supplement to “boost” the immune system. This may lead patients with HIV disease to believe echinacea would enhance their impaired immunity. Actually, the opposite is true: effects of echinacea may actually *decrease* CD4 cell counts in HIV patients, leading to increased risk of infection.^[18]

COMMONLY USED HERBAL SUPPLEMENTS

Many dozens of herbal supplements are available to be purchased over-the-counter. Discussion of all these herbal supplements is beyond the scope of this article. Listed below is a brief discussion of each of the more commonly available and used supplements, including highlights of known active constituents, pharmacology, dosing, supporting clinical literature, adverse effects, and interactions with conventional medications. The known and potential drug–herb interactions are summarized in Table 2.^[18–22]

Black Cohosh (*Cimicifuga racemosa*)

Black cohosh is also known as black snakeroot, bugbane, bugwort, rattleroot, and rattleweed. It should not be confused with blue cohosh, a uterine stimulant historically used to induce labor.^[18] Black cohosh is used to treat menopausal symptoms, including hot flashes, excessive sweating, emotional lability, and sleep changes.^[23] The exact active constituents are not known but are thought to include the *triterpene glycosides* (such as actein, 27-deoxyactein, deoxyacetylactol, and cimicifugoside), *phytosterins*, and *isoflavones* found in root extracts.^[18,23] For many years, practitioners thought that black cohosh must be estrogenic, but more recent animal and human data suggest that its pharmacology does not involve acting as an estrogen.^[23] This was confirmed by a recent controlled trial in breast cancer patients with

**Table 2** Reported and potential herb–drug interactions

Herb	Interacting drug or drug class	Effect
DHEA	Antidiabetic agents ^a	Decreased hypoglycemic effects
Garlic	ASA, NSAIDs	Additive antiplatelet effects
	Clopidogrel, ticlopidine	Additive antiplatelet effects
	Warfarin	Increased risk of bleeding
Ginger	ASA, NSAIDs	Additive antiplatelet effects
	Clopidogrel, ticlopidine	Additive antiplatelet effects
	Warfarin	Increased risk of bleeding
Ginseng	ASA, NSAIDs	Additive antiplatelet effects
	Antidiabetic agents	Additive hypoglycemia
	Clopidogrel, ticlopidine	Additive antiplatelet effects
	CNS stimulants, caffeine	Additive CNS toxicity
	Corticosteroids	Additive CNS toxicity
	Digoxin	Falsely elevated levels
	MAO inhibitors	Increased toxicity
Ginkgo	Warfarin	Increased risk of bleeding
	Anticonvulsants	Decreased antiseizure effects
	ASA, NSAIDs	Additive antiplatelet effects
	Clopidogrel, ticlopidine	Additive antiplatelet effects
	Warfarin	Increased risk of bleeding
Green tea	Warfarin	Decreased anticoagulant effects
Hawthorne	Antihypertensives	Additive hypotension
	Digoxin	Potential of (+) inotropic effects
Kava	CNS depressants, ethanol	Additive sedation, risk of coma
	Hepatotoxins	Additive hepatotoxicity
Licorice	Antihypertensives	Antagonism of hypotensive effects
	Corticosteroids	Additive mineralocorticoid effects
	Digoxin	Risk of toxicity due to hypokalemia
	Diuretics	Additive hypokalemia
Ma huang	CNS stimulants, caffeine	Additive CNS stimulation
	Digoxin	Additive toxicity
	MAO inhibitors	Hypertensive crisis
Melatonin	CNS depressants, ethanol	Additive sedation
St. John's wort	Cyclosporine	Decreased levels and decreased effect
	Digoxin	Decreased levels and decreased effect
	Indinavir, nevirapine	Decreased levels and decreased effect
	MAO inhibitors	Increased risk of MAO toxicity
	Oral contraceptives	Decreased levels and decreased effect
	Simvastatin	Decreased levels and decreased effect
	SSRIs	Increased risk of serotonin syndrome
Valerian	Warfarin	Decreased levels and decreased effect
	CNS depressants, ethanol	Additive sedation

^aAntidiabetic agents include drugs such as insulin, glipizide, glyburide, and metformin.

ASA = aspirin; NSAIDs = nonsteroidal anti-inflammatory drugs, such as ibuprofen, naproxen, and diclofenac;

CNS stimulants include drugs such as pseudoephedrine, dextroamphetamine, theophylline, and caffeine;

MAO = monoamine oxidase; CNS depressants include drugs such as benzodiazepines, barbiturates, and ethanol;

SSRIs = selective serotonin reuptake inhibitors, such as fluoxetine, sertraline, and paroxetine.

(From Refs. 18–22.)

treatment-related hot flashes found no difference in efficacy when compared to placebo.^[24] However, the compound was considered to be safe in these patients. No changes in luteinizing hormone (LH) or follicle stimulating

hormone (FSH) levels were noted between the two groups, indicating limited estrogenic activity.^[24] The most studied doses range from 20 mg to 40 mg twice daily.^[18,23] Initial effects may be seen within 2 weeks, but maximal benefit

generally takes 8 weeks of continued therapy.^[23] Black cohosh is quite well tolerated, with only mild gastrointestinal (GI) effects noted. Long-term data is not available, and patients should be advised to limit use to six months.^[18] Again, the concern that black cohosh may stimulate breast or endometrial cancer cells by acting as an estrogen is not founded based on recent data.^[23,24] However, this herb should be avoided in pregnancy as miscarriages have been reported. Black cohosh has no known herb–drug interactions.^[18] However, postmenopausal patients should be advised that black cohosh is not a direct substitute for estrogen replacement therapy, as it has undetermined benefits for osteoporosis and cardiovascular disease.^[23]

Dehydroepiandrosterone (DHEA)

Dehydroepiandrosterone is not truly an herb but rather a natural steroid product of the adrenal glands. In addition, DHEA is the steroid precursor to 50% of androgens in men, 75% of estrogens in premenopausal women, and close to 100% of estrogens in postmenopausal women. Levels peak between age 20 and 30, then decline approximately 2% per year thereafter.^[25] Because levels are known to decline with age, DHEA is often marketed as an “antiaging” supplement. There are absolutely no clinical trials published examining this effect. In addition, DHEA levels are known to be lower in many chronic disease states, including some cancers, cardiovascular disease, systemic lupus erythematosus (SLE), Alzheimer’s, and progression of HIV disease. Dehydroepiandrosterone has been studied in small trials as a treatment for fatigue in HIV patients as well as for treatment of depression in middle-aged patients and for SLE.^[25] Replacement doses in patients known to be deficient (due to long-term corticosteroid use or chronic disease) are 20 mg–50 mg per day in men and 10 mg–30 mg per day in women.^[25] Doses for the other indications listed above are much higher, ranging from 200 mg to 500 mg per day.^[25] Adverse effects are directly related to increased androgen production and include acne, insomnia, irritability, and hirsutism.^[18,25] Perhaps, the most serious potential adverse effect of DHEA is stimulation of hormone-dependent cancers such as prostate, breast, and endometrial. Because of this potential, patients with known risk factors or a personal history of these tumors should not take DHEA.^[18,25] It has not been reported to cause herb–drug interactions. However, it is a mild inhibitor of the cytochrome P450 3A4 isoenzyme system and may increase concentrations of metabolized drugs to a minor extent.^[18]

Echinacea (*Echinacea angustifolia*, *pallida*, and *purpurea*)

Echinacea has a host of other common names, including American coneflower, black Sampson, black Susans, comb flower, Indian head, Kansas snakeroot, purple coneflower, red sunflower, survey root, and Sampson root.^[18] It is used as a nonspecific immune stimulant and has several active constituents. Caffeic acid derivatives and high-molecular weight polysaccharides stimulate phagocytosis of macrophages and natural killer cells. They also increase production of tumor necrosis factor-alpha (TNF-alpha) and interleukin-1. In addition, echinacea contains alkylamides that have anti-inflammatory properties.^[26] The portions of the herb used are the dried root or the fresh juice from the root and aerial parts. The form most commercially available is the dried root in capsules. Because the active constituents are not water soluble, tinctures and teas are not likely to be as effective.^[18] The best form of echinacea is likely an alcoholic extract of the root, either 1:1 or 1:5 in 45% ethanol. Doses are usually 1 ml–2 ml taken 3–4 times a day. The most studied indications include prevention of viral upper respiratory infections (URIs) in patients at high risk, as well as adjunct treatment of URIs, to decrease severity of infection. The strongest data are with treatment, rather than prevention, and a recent review of randomized trials published since 1997 found two negative and three positive. The positive trials found that echinacea decreased the frequency, duration, and magnitude of URI symptoms.^[27] For this indication, patients should be advised to begin echinacea at the onset of symptoms and continue therapy until 24 hr after symptom resolution.^[26] For prevention, studies have examined taking echinacea daily for 8 weeks during the “cold and flu” season; however, this indication is not generally recommended due to inadequate data.^[18] Adverse effects are rarely reported, although patients may experience allergic reactions.^[26] There are also a few reports of immunosuppression with more than 8 weeks of continuous use, and long-term use should be avoided. There are no known herb–drug interactions with echinacea, but there are several herb–disease state contraindications. HIV patients should avoid using echinacea, because it may increase TNF-alpha levels, which in turn decreases CD4 counts. Also, due to the potential for immunostimulation, patients with autoimmune diseases should not take echinacea (e.g., multiple sclerosis, collagen–vascular diseases).^[18,26] Of interest, there is one controlled trial in women who took echinacea during pregnancy. More than 400 women were monitored for pregnancy outcome: 200 who took echinacea and 200 who

Alternative Medicines

did not. There was no difference in the rate of spontaneous abortion or the rate of fetal malformations, indicating echinacea may be safe for limited use during pregnancy.^[28] No other herbal product has such conventional literature published for use and exposure during pregnancy.

Evening Primrose Oil (EPO, *Oenothera biennis*)

Evening primrose oil is named for the flowers on the plant that open in the late afternoon. It is also known as king's cure-all.^[18] The seeds contain 7%–10% gamma-linoleic acid (GLA), an essential omega-6 fatty acid. The body relies on the metabolic conversion of linoleic acid to GLA, and this conversion is defective in a number of disease states, including fibrocystic breast disease, diabetic neuropathies, and various skin disorders (such as atopic dermatitis and eczema).^[18] The EPO has been studied in numerous small trials for these indications as well as for premenstrual syndrome. Trials in various breast diseases have been positive, although it may take 6 mo or more to see effects. Doses range from 2 g to 4 g EPO (which is 200 mg–400 mg GLA) per day in 2–3 divided doses. Doses for neuropathy treatment are generally higher.^[18] At all these doses, EPO is well tolerated, producing only mild GI upset and headache. Patients should take doses with food. In addition, EPO has no known contraindications and no reported herb–drug interactions.^[18]

Garlic (*Allium sativum*)

The active component of garlic is formed when alliin, a compound in the bulbs, is converted by the enzyme allinase to allicin.^[18] During food preparation, this conversion takes place when the bulbs/cloves are crushed. The conversion may also take place in the GI tract, although the conversion is reduced in the presence of stomach acid. Fresh garlic intake is considered to be the most efficacious way to consume this herb for disease–treatment indications, although many forms of tablets, capsules, tincture, and juices are available. For nonfresh intake, tinctures and oils should be avoided due to instability of allicin. Enteric-coated tablets, prepared by drying the crushed bulbs and then compressing them into tablets, are also likely effective, as they bypass the effect of stomach acid.^[18] Garlic has been most studied for the treatment of dyslipidemias and hypertension. Its effects on blood pressure are not well substantiated; however, in a recent meta-analysis of 13 randomized trials, garlic was found to produce modest reductions (20%) in total cholesterol and triglycerides.^[29] Doses used range from

600 mg to 900 mg per day, which is roughly equivalent to 4 g of fresh garlic cloves per day.^[29] In addition, a recent review of 45 trials found not only reductions in total cholesterol, low density lipoprotein (LDL) cholesterol, and triglycerides with garlic therapy, but also noted decreases in platelet aggregation. No effects on blood glucose were seen.^[30] Garlic has minimal adverse effects, with the exception of GI effects (such as heartburn and flatulence) and the characteristic body odor. Contact dermatitis has been reported with extensive handling of the fresh cloves.^[18] Again, garlic inhibits platelet aggregation that may cause herb–drug interactions with other antiplatelet and anticoagulant drugs.^[18]

Ginger (*Zingiber officinale*)

The part of this herb used is the root that contains 1%–3% gingerols. When the root is dried, the gingerols are converted to shogaol and zingerone, but the clinical significance of this conversion is not known.^[31] The gingerols are thought to stimulate upper GI motility, similar to the effects of metoclopramide.^[31] This gives rise to ginger's most common indication, that of an antiemetic. Ginger has no known central effects on the chemoreceptor trigger zone in the brain. Dosing for motion sickness and morning sickness is 1 g–4 g per day fresh ginger or 500 mg–1000 mg as dry powdered root. Daily intake is generally divided into 2–4 doses. For motion sickness, ginger has been shown to be superior to placebo and even to dimenhydrinate in some small trials.^[31] A recent randomized trial in 70 pregnant women with morning sickness also found ginger to be superior to placebo for reducing both nausea and vomiting.^[32] Ginger has also been studied in postoperative nausea/vomiting but with less positive results. It has also been marketed as a treatment for osteoarthritis, but the data for this indication are weak at best.^[18,31] No significant adverse effects have been observed with ginger. It may be a mild inhibitor of platelet aggregation, and therefore, the potential for herb–drug interactions exist.^[18] These antiplatelet data are not as strong as for garlic, ginseng, and ginkgo.

Ginkgo (*Ginkgo biloba*)

The ginkgo tree is also called the kew tree, maidenhair tree, and fossil tree.^[18] It is the oldest known tree species, and the largest commercial farm of ginkgo trees is in Sumter, South Carolina. The most common indications for ginkgo are related to increasing mental capacity, as well as to treat cerebral and peripheral vascular disease. This may be due to touted benefits of flavonoids and terpenoids (ginkgolides and others) that may inhibit

platelet-activating factor, increase cerebral circulation, inhibit arterial spasms, decrease capillary permeability and fragility, and improve brain tolerance to hypoxia. They may also act as free radical scavengers.^[18] It is recommended that extracts from the seeds and leaves be used that have been standardized to 24% flavonoids and 6% terpenoids. The most studied tablets contain 40 mg of this extract. Use for general improvements in cognitive function are not well studied; however, there have been several trials for Alzheimer's-type dementia. Doses from 40 mg to 80 mg 3 times daily have been shown to improve cognitive skills, although results may take 3 mo or longer to be seen.^[18,33] In addition, a recent meta-analysis examined the results of eight randomized trials treating intermittent claudication with ginkgo 40 mg 3–4 times daily. This dose significantly improved pain-free walking distances.^[34] The reported adverse effects of ginkgo include nausea/vomiting, diarrhea, and seizures with overdose or excessive intake of the seeds (rather than the leaves).^[18] There have also been case reports of excessive postoperative bleeding, likely due to the antiplatelet effects of ginkgo.^[35] Due to these antiplatelet effects, there is the potential for herb–drug interactions with conventional anticoagulant and antiplatelet agents.^[18]

Ginseng

The herb known as “ginseng” is representative of the dangers of inconsistent nomenclature. There are actually three herbs that are known by this common name: American or western ginseng (*Panax quinquefolius*), Asian or Chinese ginseng (*Panax ginseng*), and Siberian ginseng (*Eleutherococcus senticosus*), a very different albeit related plant species.^[18] For the purposes of this text, ginseng refers to both American and Asian, as they have very similar therapeutic and adverse effects. The active components in ginseng are 12 ginsenosides isolated from the root.^[18] Ginseng is marketed to enhance both physical and mental performance, and certainly the ginsenosides are CNS (central nervous system) stimulants. However, data for the therapeutic effectiveness of these compounds are limited. A recent trial in 83 otherwise young healthy adults (mean age 26 years) compared two doses of ginseng (200 mg and 400 mg per day) to placebo.^[36] There were no differences noted in psychological well-being.^[36] Adverse effects reported for ginseng are numerous and include chest pain, palpitations, hypertension, headache, insomnia, irritability, nervousness, hypoglycemia, impotence, and GI effects (such as nausea, vomiting, and diarrhea). Reported and potential drug interactions are related to ginseng's antiplatelet and

CNS stimulant effects.^[18] Due to these adverse effects that occur more frequently than with other previously discussed herbals, ginseng should be used cautiously, particularly in patients with a history of cardiovascular or CNS disease.

Glucosamine/Chondroitin

Glucosamine is an endogenous aminomonosaccharide used in the synthesis of proteoglycans in cartilage, which are depleted in osteoarthritis.^[37] Current conventional treatment of osteoarthritis is supportive only and includes treatment with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). These drugs decrease the pain and inflammation associated with the disease, but they do not change the overall disease process.^[37] Glucosamine, on the other hand, may increase cartilage production, or at least slow breakdown, as well as provide mild anti-inflammatory effects.^[37] Chondroitin is extracted from the cartilage in bovine trachea and may increase collagen synthesis in cartilage.^[18] Short-term trials with each agent used individually have shown modest results compared to placebo and NSAIDs.^[18] A meta-analysis of 15 randomized, placebo-controlled trials was positive overall in favor of glucosamine/chondroitin, but the authors remarked that bias was likely as almost all the trials were sponsored by the manufacturer.^[38] They conceded that efficacy in osteoarthritis appears “probable.”^[38] Unfortunately, the additional benefit of chondroitin to oral tablets is minimal at best, because glucosamine is 95% absorbed but chondroitin has minimal oral bioavailability.^[18] The combination is well tolerated, producing only mild headache, nausea/vomiting, and occasional rash.^[18] The Arthritis Foundation does not recommend the use of this supplement, but due to few adverse effects, a trial in patients intolerant to other conventional analgesics would not be unreasonable. Doses are often weight-based and range from 1000 mg to 2000 mg per day, divided.^[18] Unfortunately, there are no long-term studies published with this long-term condition. Animal data have reported hyperglycemic effects, so diabetic patients should monitor blood glucose levels closely.^[18]

Grapeseed (*Vitis vinifera*)

Grapeseed extracts from the seeds of the herb contain flavonoids, as well as some essential fatty acids and tocopherols. The flavonoids are considered as the primary active constituents, inhibiting lipid peroxidation. Tocopherols, related to vitamin E, are also antioxidant in

Alternative Medicines

nature.^[18] The most studied patient population with grape-seed is cardiovascular disease patients, particularly patients with dyslipidemias. Doses range from 25 mg to 300 mg daily. No adverse effects or drug interactions have been reported for grape-seed, although conventional clinical data are limited.^[18]

Green Tea (*Camellia sinensis*)

Green tea is made in a curing process that withers and then ferments the leaves of this herb before drying them. This process is thought to preserve the activity of the polyphenols contained in the fresh leaves. Most teas are standardized to contain 60% polyphenols, which are purported to have antioxidant, lipid-lowering, and potentially anticancer effects.^[18] Green tea also contains 1%–4% methylxanthines, including caffeine.^[18] Clinical trials looking at the efficacy of green tea are few, but it is thought that significant consumption (6–10 cups per day) is necessary to see effects.^[18] A recent phase 1 trial in patients with refractory solid tumors found no objective responses with 5% stable disease.^[39] The dose-limiting toxicities were caffeine-related, and the maximum tolerated dose was equivalent to 7–8 cups per day of green tea.^[39] Dairy products may inhibit the polyphenols in green tea, so concurrent consumption should be avoided. The only reported adverse effects are rare allergic reactions. Patients should be advised, however, of the modest caffeine content of green tea, particularly because many herbal teas are “caffeine-free.”^[18] Green tea may contain significant vitamin K content as well; therefore, the effects of warfarin may be inhibited.^[40]

Kava (*Piper methysticum*)

Kava is a member of the black pepper family and is also known as ava, awa, kew, sakaw, tonga, and yagona.^[18] The root contains kavapyrones that inhibit the limbic system, and they are sedating and may elevate mood to a minor degree. Kava is marketed as an anxiolytic and as treatment for depression and insomnia.^[41] Doses used range from 60 mg to 120 mg daily at bedtime.^[18] Unfortunately, several potentially dangerous effects have been recently attributed to kava. Clearly, sedation, visual changes, and decreased motor reflexes are potential toxicities. Coma has even been reported with concurrent use of kava and alprazolam.^[41] In addition, the FDA is investigating at least 25 cases in Europe of hepatotoxicity attributed to kava.^[16] Caution should be exercised when using kava with other CNS depressants, especially benzodiazepines, or hepatotoxins. Kava does not appear to cause psychological dependence.^[18]

Ma Huang (*Ephedra sinica* and *nevadensis*)

Ephedra has also been called Brigham tea, desert tea, herbal fen-phen, joint fir, Mexican tea, Mormon tea, natural ecstasy, popotillo, sea grape, squaw tea, teamster tea, and yellow horse.^[18] The active component, ephedrine, was isolated in the 19th century and was used extensively in the 20th century in nasal decongestants and as a CNS stimulant. Extracts of ephedra seeds and stems contain 0.5%–2.5% alkaloids, not only including ephedrine, but also pseudoephedrine, methylephedrine, and norephedrine. All are CNS stimulants, with effects similar to amphetamines and caffeine.^[18] Although ephedra is no longer available in conventional nasal decongestants due to the risk of toxicity, it is commonly found in many herbal weight-loss products. This is due to its ability to suppress the appetite and increase metabolic rate. Ephedra is available as capsules, tablets, teas, and tinctures. The FDA advises consumers not to take more than 24 mg in 24 hr and to limit use to no more than 7 days.^[18] The primary problem with ephedra is the high potential for toxicity. It is a CNS stimulant, and as such, can cause anxiety, confusion, headache, insomnia, and irritability. These effects are greatly increased when ephedra is taken with caffeine. In addition, ephedra has significant cardiovascular effects, including reported hypertension, tachycardia, myocardial infarction, and cardiac arrest, usually when the labeled maximum daily dose is exceeded. These potentially fatal effects have been reported even in previously healthy young adults. A recent review of 98 events thought to be possibly or probably related to ephedra intake in a 2-yr period (1997–1999) found 47% cardiovascular effects (primarily hypertension, as well as palpitations and tachycardia), as well as 18% CNS effects, including strokes and seizures. Ten deaths were reported.^[42] All of these adverse effects also lead to potential herb–drug interactions with other stimulant drugs. In addition, patients with glaucoma, cardiovascular disease, thyroid disease, psychiatric conditions, diabetes, or prostate disease should avoid using ephedra. Pregnant women should also not take this supplement due to the potential for uterine contractions and preterm labor.^[18] The FDA is still investigating all reports of serious effects (more than 800 to date) due to ephedra and may ban this product from the market in the future.^[18]

Melatonin (N-Acetyl-5-methoxytryptamine)

Melatonin is not an herb but rather is a naturally occurring hormone produced in the pineal gland from tryptophan. It is also commercially synthesized. Endogenously,

melatonin is released during sleep periods, and levels are low during the day.^[18,43] As a supplement, melatonin has been most studied as a preventative/treatment for jet lag and as a sedative-hypnotic. For jet lag, patients are advised to take 5 mg daily at bedtime beginning three days prior to travel and continuing for three days after travel is complete.^[18,43] Levels of melatonin decrease with age, so it has been studied in elderly patients with sleep disorders. This patient population is more sensitive to the effects of melatonin; therefore, they should start with lower doses, usually 1 mg–2 mg at bedtime.^[43] Patients with liver disease should use melatonin cautiously, as clearance of the compound is impaired.^[43] Adverse effects reported with melatonin use include headache, confusion, sedation, and mild hypothermia. Concurrent use of CNS depressants, including alcohol, should be avoided.^[18,43]

Milk Thistle (*Silybum marianum*)

Milk thistle is also known as Our Lady's thistle, Mary thistle, Marian thistle, and St. Mary's thistle.^[18] The active constituent, silymarin, has been isolated and the structure determined for many years. Only the fruit of the herb contains the active ingredient, 1%–4% as a mixture of three related compounds: silibinin, silidianin, and silychristin.^[44] Silymarin may act to stabilize hepatocyte membranes, as well as stimulate RNA polymerase, aiding liver regeneration after cell damage. It is also thought to be a free radical scavenger.^[18] Interestingly, milk thistle is the only known antidote for poisoning by the "death cap" mushroom, *Amanita phalloides*. The dosing for this poisoning is intravenous silymarin, which is only available in Europe.^[18] Milk thistle is also marketed and studied as a treatment for acute and chronic alcoholic and viral hepatitis, as well as a treatment for hepatotoxicity from drugs such as haloperidol and prochlorperazine.^[44] Decreased complication rates have been observed in acute viral hepatitis, as well as improvement in liver function tests in alcoholic hepatitis. However, no survival benefit with milk thistle has been observed.^[44] The most studied dose for liver diseases is 140 mg silymarin three times daily, which are 200 mg milk thistle extract doses standardized to 70% silymarin.^[18] Teas should be avoided as a dosage form due to silymarin being practically water-insoluble.^[44] Milk thistle has no known herb-drug interactions and causes minimal toxicity, including diarrhea and occasional allergic reactions. Milk thistle should be avoided in pregnancy due to its ability to cause uterine contractions.^[18]

S-Adenosylmethionine (SAME)

This is an endogenous substance produced from adenosine triphosphate and the amino acid methionine. It is naturally involved in a range of biological processes.^[45] As a supplement, it is most studied in the treatment of depression, as well as treatment of liver disease. In a recent meta-analysis, doses of 400 mg–1600 mg per day were found to be superior to placebo and as efficacious as moderate-dose tricyclic antidepressants.^[45] A few small trials in patients with liver disease have demonstrated improvement in liver enzymes with doses of 1600 mg per day or more.^[45] Due to limited bioavailability, SAME was previously only available intravenously. Enteric-coated tablets are now available as well, but bioavailability studies are lacking. Doses should be titrated, starting with 200 mg once daily and increasing by 200 mg increments every 1–2 weeks.^[45] The SAME is well tolerated, with only mild GI distress noted as an adverse effect and no known drug interactions.^[45]

Saw Palmetto (*Serenoa repens*)

Saw palmetto is also known as the cabbage palm and American dwarf palm tree.^[18] The ripe berries are thought to contain the active ingredients (perhaps fatty acids and sterols); however, the exact active components are not known.^[18] Saw palmetto is mainly used in the treatment of benign prostatic hypertrophy^[46] due to postulated inhibition of 5-alpha-reductase, the same mechanism as the conventional drug finasteride. The dose most studied is 160 mg twice daily. In a recent meta-analysis of 18 randomized trials, saw palmetto improved urologic symptoms to a rate similar to finasteride and better than placebo.^[46] Saw palmetto is well tolerated, causing mild abdominal pain, nausea/vomiting, and occasional decreased libido.^[46] Due to the risk of birth defects, pregnant women should avoid the use of saw palmetto.^[18] No known herb-drug interactions are reported; however, saw palmetto will reduce prostate-specific antigen (PSA) levels. This test is used to screen for prostate cancer; therefore, men at risk of this disease should avoid saw palmetto due to the risk of a false negative result.^[18]

St. John's Wort (*Hypericum perforatum*)

This herb is also known as St. Joan's wort, klamath weed, and goatweed.^[18] It has historically been used for many purposes, but most recently it is marketed as an antidepressant. In fact, it outsells all conventional antidepressants in Germany. The active constituent is hypericin that seems to act as a weak monoamine oxidase

MAO inhibitor and a selective serotonin reuptake inhibitor (SSRI). Dopamine and norepinephrine uptakes are also mildly inhibited.^[18] St. John's wort is available in many forms, as a tablet, tea, tincture, and the raw dried herb. For best results, a tablet standardized to contain 0.3% hypericin should be taken; Kira[®] by Lichtwer Pharma is the most extensively studied.^[18] Randomized, placebo-controlled trials using 300 mg of St. John's wort three times daily have found it to be superior to placebo in mild to moderate depression. Response rates are generally regarded as inferior to conventional antidepressants, including tricyclic antidepressants and SSRIs.^[47,48] In addition, St. John's wort is not without toxicity. Reported adverse effects include dizziness, headache, sleep changes, restlessness, dry mouth, and photosensitivity.^[18] Perhaps most significant are the reported herb-drug interactions. St. John's wort is a significant inducer of the cytochrome P450 3A4 isoenzyme system, which is responsible for metabolizing up to 60% of conventional drugs. There are several case reports of clinically significant decreases in serum cyclosporine concentrations, leading to transplanted organ rejection.^[49,50] Also, decreases in indinavir concentrations have been reported, which could potentially lead to HIV treatment failures and resistance.^[51] Other drugs metabolized via 3A4, including warfarin, digoxin, oral contraceptives, and simvastatin could potentially have levels decreased by St. John's Wort.^[18] Finally, because of its weak MAO inhibition and serotonin re-uptake effects, St. John's wort should not be taken concurrently by patients on MAO inhibitors or SSRIs.^[18]

Valerian (*Valeriana officinalis*)

Valerian has also been called All Heal, amantilla, Baldrianwurzel, and setwell.^[18] The root extract contains iridoid triesters (valepotriates) that stimulate the release of gamma-aminobutyric acid (GABA).^[52] This pharmacology is similar to that of the benzodiazepine sedatives.^[18] Animal studies confirm this pharmacology, as valerian attenuates benzodiazepine withdrawal symptoms in rats.^[52] As a sedative/hypnotic, valerian doses range from 400 mg to 900 mg taken at bedtime. Placebo-controlled trials are small and have mixed results. Some have shown increased quality of sleep and decreased sleep latency, while others have shown no difference vs. placebo.^[52] Data for using valerian as an anxiolytic are equally weak. Patients desiring to take valerian prior to an anxiety-producing event should be advised of the questionable efficacy and that the doses are much smaller than as a sedative, 100 mg taken 90 min prior to the event.^[52] Adverse effects include sedation, visual changes,

headache, rare allergic reactions, nausea/vomiting, and case reports of hepatotoxicity. Use with other CNS depressants, including alcohol, should be avoided.^[18]

Potentially Unsafe Herbs

Any herb may be unsafe or cause serious adverse effects when used incorrectly. The herbs listed in Table 3, however, have been more commonly reported to cause serious or life-threatening effects. Many are on the FDA's official list of unsafe herbs.^[18]

Many unsafe herbs are anticholinergic in nature, often due to significant hyoscyamine (and to a lesser extent, scopolamine) content. This includes belladonna, the nightshades, henbane, jimsonweed, and mandrake. These herbs cause a constellation of symptoms often referred to as "Hot as a hare, blind as a bat, dry as a bone, red as a beet, mad as a hatter." This includes confusion, hallucinations, agitation, elevated temperature, hypertension, tachycardia, mydriasis, dry mucous membranes, dry/flushed skin, and nausea/vomiting. Ultimately, respiratory arrest, seizures, and life-threatening arrhythmias can occur.^[53]

One herb, the calabar bean, actually causes cholinergic toxicity (as seen with pesticide overdoses) due to the physostigmine content in the ripe seeds. This toxicity includes bradycardia and hypotension, potentially leading to cardiac and respiratory arrest.^[18]

Several herbs have significant content of cardiac (digitalis) glycosides, including A Scotch broom, Canadian hemp, hedge mustard, Lily of the Valley, monkshood, wallflower, and foxglove, of which the conventional medication digoxin is derived. These herbs can cause bradyarrhythmias and heart block.^[18]

Other potentially unsafe herbs have varying degrees of neurotoxicity, GI toxicity, and hepatotoxicity. Many cause multiorgan toxicity. Nux vomica contains strychnine in the seeds and bark. Jalap and castor bean are cathartic laxatives. Callamus, chapparal, and comfrey are potential hepatocarcinogens.^[54] Autumn crocus contains colchicine, and lobelia has nicotine-like effects. All of these herbs should be avoided, and their high potential for toxicity re-enforces the idea that "natural" certainly does not always mean "safe."^[18,53,55,56]

PATIENT ASSESSMENT AND COUNSELING TIPS

When assessing a patient who wants to begin an herbal supplement, both past medical history as well as concurrent conventional medication used should be taken into account for potential interactions, as discussed

**Table 3** Potentially unsafe herbs

Harmful effects	Common name	Latin binomial	Toxic constituents	Serious adverse effects	Comments
Anticholinergic	Belladonna	<i>Atropa belladonna</i>	0.3%–0.6% hyoscyamine in leaves and root	Anticholinergic toxicity	Toxic effects with 5 mg–50 mg
	Bittersweet nightshade	<i>Solanum dulcamara</i>	Solasonine in stem and unripe berries	Anticholinergic toxicity	Toxic effects with ≥ 10 berries; fatal adult dose ~ 200 berries
	Black nightshade	<i>Solanum nigrum</i>	2% solasonine in stem, root, unripe berries	Anticholinergic toxicity	Less toxic than belladonna
	Henbane	<i>Hyoscyamus niger</i>	0.04%–0.28% hyoscyamine in leaves	Anticholinergic toxicity	More sedating than belladonna
	Jimsonweed	<i>Datura stramonium</i>	0.1%–0.6% hyoscyamine in ripe seeds, leaves, flowers	Anticholinergic toxicity	Seeds may be chewed or leaves smoked as cigarettes
	Mandrake	<i>Mandragora vernalis</i>	0.4% hyoscyamine in root	Anticholinergic toxicity	More sedating than belladonna
Cholingeric	Calabar bean	<i>Physostigma venenosum</i>	Physostigmine in ripe seeds	Cholinergic toxicity	Chewing seeds releases more physostigmine
Cardiotoxicity	(Scotch) broom	<i>Cytisus scoparius</i>	2% tyramine and 0.01%–0.22% sparteine in aerial parts	(–) inotrope, quinidine-like antiarrhythmic	Toxic effects with ≥ 30 g raw herb
	Canadian hemp	<i>Apocynum cannabinum</i>	Cardioactive glycosides in root and aerial parts	Bradycardia, A–V block	Less cardiotoxic than foxglove
	Foxglove	<i>Digitalis purpurea</i>	Cardioactive glycosides in ripe seeds, leaves, flowers	Bradycardia, A–V block, miosis	<i>Digitalis ianata</i> is major source of digoxin in the United States.
	Hedge mustard	<i>Sisymbrium officinale</i>	Cardioactive glycosides in aerial parts	Bradycardia, A–V block	Avoid confusion with other mustard species
	Lily of the valley	<i>Convallaria majalis</i>	Cardioactive glycosides in root, flowers, leaves	Bradycardia, A–V block	Water from the cut flowers also toxic
	Monkshood	<i>Aconitum napellus</i>	Aconitine in root, leaves, flowers	Hypothermia, bradycardia, respiratory arrest	Fatal adult dose ≥ 2 mg; topical use also toxic
	Wallflower	<i>Cheiranthus cheiri</i>	Cardioactive glycosides in ripe seeds and flowers	Bradycardia, A–V block	
Neurotoxicity	Nux vomica	<i>Strychnos nuxvomica</i>	2%–5% strychnine in ripe seeds and bark	Hyperthermia, agitation, seizures	Toxic effects with 30 mg–50 mg; fatal adult dose 1 g–2 g
	Wormwood	<i>Artemisia absinthium</i>	Thujone in the volatile oil from leaves and flowers	Delirium, psychosis, renal failure, xanthopsia	Thujone related to camphor

GI Toxicity	Bloodroot	<i>Sanguinaria Canadensis</i>	4%–7% sanguinarine in root	Tissue irritation and necrosis with topical use	Poorly absorbed
	Castor bean	<i>Ricinus communis</i>	42%–55% castor oil and 0.1%–0.7% ricin in ripe seeds	Cathartic laxative	Chewing seeds releases the ricin
	Jalap	<i>Ipomoea orizabensis</i>	12%–15% polymeric ester glycosides in root	Cathartic laxative	
	Marsh marigold	<i>Caltha palustris</i>	Protoanemonin in fresh flowers	Skin blistering, mucous membrane irritation	Dried flowers have little toxic effect
	Queen's delight	<i>Stillingia sylvatica</i>	Diterpene esters in juice of root	Inflammation and mucous membrane irritation	
Hepatotoxicity	Calamus	<i>Acorus</i> spp: <i>A. calamus</i> , <i>A. americanus</i> , <i>A. angustatinus</i>	β -Isoasarone in oil from root: calamus <10%, americanus 0%, angustatinus > 80%	Potential hepatocarcinogen	Active component related to reserpine
	Chaparral	<i>Larrea tridentata</i>	Nordihydro-guaiaretic acid in leaves	Cholestasis, potential hepatocarcinogen	
	Comfrey	<i>Symphytum officinale</i>	0.03%–0.6% UPAs in root and leaves	Veno-occlusive disease, potential hepatocarcinogen	Safe for use topically to unbroken skin for <10 days
	Germander	<i>Teucrium chamaedrys</i>	Teucrin A in aerial parts	Liver necrosis	Safe for use in small amounts to flavor beverages
	Life root	<i>Senecio nemorensis</i>	0.01%–0.1% UPAs in aerial parts	Veno-occlusive disease, potential hepatocarcinogen	
Multi-organ Toxicity	Arnica	<i>Arnica montana</i>	Sesquiterpene lactones in flowers	Hypertension, arrhythmias, muscle paralysis	May be safe for topical use
	Autumn crocus	<i>Colchicum autumnale</i>	$\geq 0.4\%$ colchicine in flowers and ripe seeds	Renal and bone marrow failure, hepatotoxicity	Fatal adult dose 5 g of seeds
	Cotton	<i>Gossypium herbaceum</i>	Gossypol in seeds and root	Heart failure, inhibition of spermatogenesis	Small amounts of cotton seed oil in foods are safe
	Daffodil	<i>Narcissus pseudonarcissus</i>	Lycorine in bulb, leaves, flowers	Respiratory arrest, topical irritation	
	Lobelia	<i>Lobelia inflata</i>	6% lobeline in leaves and seeds	Hypothermia, anxiety, seizures, arrhythmias, respiratory arrest	Nicotine-like, toxic effects with 1 g; fatal adult dose 4 g
	Mayapple	<i>Podophyllum peltatum</i>	20% podophyllotoxin in root and resin	Ataxia, seizures, psychosis, coma, mucous membrane irritation, bloody diarrhea	Ripe fruits are not toxic; etoposide is a semisynthetic derivative

(Continued)

**Table 3** Potentially unsafe herbs (Continued)

Harmful effects	Common name	Latin binomial	Toxic constituents	Serious adverse effects	Comments
	Mistletoe	<i>Viscum album</i>	2% viscotoxins in leaves, berries, branches	Delirium, seizures, hypotension, cardiac arrest	Lives as a parasite on the branches of other trees
	Poison hemlock	<i>Conium maculatum</i>	Coniine in leaves, berries, flowers	Mydriasis, dizziness, respiratory arrest	Fatal adult dose 30 g berries or 100 g leaves
	Wahoo	<i>Euonymus atropurpureus</i>	Unknown toxic compound in root bark, seeds, berries	Tonic-clonic spasms, coma, hypotension, cardiac arrest	
	Wild cherry	<i>Prunus virginiana</i>	Amygdalin in leaves, seeds, stem	Headache, muscle spasms, coma, respiratory arrest	Converted to cyanide in the GI tract
	Wormseed	<i>Chenopodium ambrosioides</i>	80% ascaridole in distilled oil of seeds, berries, aerial parts	Vertigo, seizures, respiratory arrest, hypotension, cardiac arrest	Oil may explode when heated
	Yellow jessamine	<i>Gelsemium sempervirens</i>	Gelsamine alkaloids in root	Dizziness, mydriasis, seizures, bradycardia, muscle paralysis, respiratory arrest	Fatal adult dose 4 ml extract or 2 g–3 g root
	Yohimbe	<i>Pausinystalia yohimbe</i>	6% yohimbine in bark	Mydriasis, anxiety, tremor, α -2 adrenergic block with hypertension, cardiac arrest	

UPAs = unsaturated pyrrolizidine alkaloids.

(From Refs. 18, 53–56.)

before. Patients should be counseled to inform the pharmacist of all medications being taken, both conventional and otherwise. They should be told that herbals may be helpful or harmful and that limited efficacy data are usually available that is done in a controlled, scientific manner. If the pharmacy practitioner feels that the supplement is safe to be taken by the patient, then several counseling points should be stressed to maximize the potential of taking a quality supplement product. Multi-ingredient products should generally be avoided unless the patient is under the care of an herbalist. Labels should list both the common and Latin names, as well as the name and address of the manufacturer. It is likely better to purchase a supplement made by a reputable, well-known manufacturer who has a history of conforming to GMPs. The patient should be told to be aware of the different dosage forms available and that not all herbals work best when taken as a tablet. "Whole herb" products are generally ground plant parts and are not standardized at all. They should be avoided. Of course, patients should be cautioned to not believe every efficacy claim made for supplements. Finally, patients should be told to promptly report any adverse effects they think may be due to the supplement.

ALTERNATIVE MEDICINE RESOURCES

Of course, published review articles, clinical trials, and case reports can be found on Medline. To aid the pharmacy practitioner in evaluating the potential safety and efficacy of various herbal products, the following is a list of additional reputable resources.^[57,58]

CONCLUSION

Use of alternative medicine is on the rise, with herbal medicine being one of the fastest growing practices. Herbal medicines are not held to the same efficacy and safety standards as conventional medicines, but are rather sold as dietary supplements under the DSHEA of 1994. Limi-

tations of this legislation include: nonstandard botanical nomenclature, little guarantee of GMPs, the burden of safety being on the FDA rather than the manufacturer, and efficacy data lacking. Nonetheless, dangerous adverse effects and herb–drug interactions are being reported with increasing frequency. Current pharmacy practitioners have not received formal training in herbal medicine, yet they need to be familiar with herbal uses, dosing, toxicities, contraindications, and potential drug interactions. This is necessary to help patients who choose to use supplements safely. Echinacea, garlic, ginseng, ginkgo, St. John's wort, ma huang, and valerian are among the most commonly used supplements, but there are many others readily available with potentially harmful effects. Fortunately, in addition to conventional periodicals, a number of reputable herbal texts and journals are available to provide the pharmacy professional with reliable herbal drug information.

James E. Akers

Akers Kennedy & Associates, Kansas City, Missouri, U.S.A.

INTRODUCTION

Aseptic processing is a widely used methodology in the health care industry for the preparation of sterile materials. The term aseptic processing as it is applied in the pharmaceutical industry refers to the assembly of sterilized components and product in a specialized clean environment. The clean environment may be a conventional human scale classified clean rooms or an environment engineered to further reduce the likelihood of contamination by reducing (or as much as is possible eliminating) direct human contact with the product and components being assembled "aseptically." The idea of sterile products manufactured aseptically is inherently contradictory, a demonstrably sterile product cannot be produced aseptically using even the most advanced technology available today. Nevertheless, on any given day millions of putatively sterile dosage form units are produced using aseptic techniques that in the literal sense are inadequate to achieve sterility. A sterile product is one that is free from all living organisms, whether in a vegetative or spore state. This is an absolute condition, something cannot be partially or nearly sterile, the presence of a single viable organism represents a failure of the product, and the systems (environment, equipment, and procedures) used to produce it. Asepsis, that state in which all aseptically filled sterile products are manufactured, cannot be established as "sterile." Asepsis is commonly defined as a condition in which living pathogenic organisms are absent.

Putting aside the classical definitions, one must consider the real difficulty in establishing an aseptic environment, let alone a sterile one. The practitioner is left with an insurmountable task, to somehow create an environment free of any organisms, but also one (with the exception of isolators) in which personnel must be present to perform critical functions. The problem is further compounded if it is recalled that personnel are considered the single greatest source of microbial contamination in aseptic processing. Recent experiments

have shown that personnel clothed in new, sterile clean room garments slough viable contamination at a rate of roughly one viable particulate to 10,000 nonviable particles. During slow deliberate movements with the best possible clothing, operators will slough particulate and viable organisms. Therefore, the probability of human borne microbial contamination being released in the conventional clean room is one over the course of any reasonably long operational shift. With this fact in mind, how then is one to accomplish a truly sterile or even aseptic environment? Especially when we must consider that many organisms that are normally nonpathogenic, can under certain circumstances become opportunistically pathogenic. Among those circumstances are a debilitated condition of general health in the patient, or, as is increasingly common, immunological insufficiency due to age or pre-existing condition.

Other than the obvious considerations of proper facility design, sterilization validation, and sanitization procedures (all of which are discussed elsewhere in this encyclopedia), the focus of attention must be on the personnel and the activities which they must perform. These actions are broadly termed, aseptic technique, and like any other human activity they can be accomplished in a variety of ways. In order to better understand aseptic technique, some general guidance and examples of good and bad technique can be used to delineate what should and should not be permitted.

The fundamental concept behind every aseptic processing activity is that nonsterile objects must never touch sterile objects. This is often accomplished by the establishment of a "sterile field" in which the core activities are performed. All of the surfaces of the gownned human operator must be always considered nonsterile. Nonsterile objects including the operators hands must never be placed between the source of the air and a sterile object. The operators' hands and arms must always be kept at a level beneath that of open product containers. Sterile components should under no circumstances be touched directly with gloved hands, a sterilized tool should always

used for this purpose. Since gloved hands and arms will enter the sterile field they must never touch walls, floors, doors, etc. Strenuous lifting and moving of tanks, trolleys, etc. must not be done by operators assigned to work within or near the sterile field, because the more strenuous the activity the higher the level of particle generation, and at least some of the particulate released by the operator will surely be viable microorganisms.

Some of the techniques to avoid include: reaching over exposed sterile objects to make adjustments beyond them; correcting a stopper feed problem with a gloved hand; touching face, eye shield, or any other nonsterile object with gloves; taking an air sample directly over open containers; continuously standing inside flexible partitions that mark the boundary of the sterile field; breaking up clumps of components with gloved hands. Each of these actions exposes the sterile objects to undue risk of contamination from the personnel. Certainly there are more ways to contaminate the “sterile field” than we can imagine. For this reason, the procedures used in and around the “sterile field” must be carefully defined and followed closely by all personnel. These procedures should follow the general principles outlined above and are evaluated in a media fill simulation and performed in an identical fashion during aseptic processing. It is beneficial to define in writing how each procedure is to be performed and train the operators in these exact procedures.

Worst Case

No discussion of aseptic processing validation can be considered complete without some mention of “worst case.” As initially defined by the FDA, worst case included consideration of numbers of personnel, temperature, relative humidity, and other aspects (1). This aspect has been adopted with some degree of modification by industry which has included some, but certainly not all of the FDA guidance. Some of the more common worst case situations which industry employs include: number of personnel, maximum hold time for containers and other items prior to filling, number and type of interventions performed. It is important to note that the determination of worst case conditions in a aseptic processing has been largely intuitive and highly subjective. Quantitative risk analysis is rarely if ever undertaken to establish and categorize actual modes of failure. Thus, worst case conditions for tests are established largely by precedence rather than actual data. The most significant worst case condition that is employed is the use of a microbiological growth media itself. Because the majority of aseptic formulations have either a preservative system and some

products are inherently inhibitory or nonsupportive of microbial growth, the media represents a substantially more favorable environment for the survival of microorganisms. The protocol prepared for the aseptic processing validation effort should delineate where worst case type considerations have been incorporated into the experimental plan. Throughout this document, recommendations will be made to worst case assumptions where choices in the definition of the validation effort must be made.

PREREQUISITES

The validation of aseptic processing should be preceded by the formal validation of the various systems, which contribute to the sterility assurance of the materials to be produced. In essence that mandates that the facility, HVAC system, sterilization procedures for the product contact surfaces, equipment, components and product, sanitization/disinfection procedures for the suite, and personnel gowning. Merely listing the activities, which must be completed, serves to indicate the magnitude of the effort required to prepare for the aseptic processing validation effort. It is sometimes tempting to begin the validation of aseptic processing while these tasks are still underway, especially when one considers that it is universally accepted that the primary source of microbial contamination in an aseptic process are those activities which are performed by gowned personnel (Table 1).

It should be evident that virtually all of the items that top the list are either performed by or corrected by the human operator. The impact of the remaining factors is widely acknowledged to be of secondary consideration.

Table 1 Most likely sources of microbial contamination in aseptic processing^a

1. Personnel borne contaminants
2. Human error
3. Non-routine operations during aseptic process
4. Assembly of sterile equipment prior to use
5. Mechanical failure
6. Inadequate or improper sanitization
7. Transfer of materials within APA
8. Routine operations during aseptic process
9. Airborne contaminants
10. Surface contaminants
11. Failure of sterilizing filter
12. Failure of HEPA filter
13. Inadequate or improper sterilization

^aFrom most to least likely. (From Ref. 2.)

Yet proceeding with the validation of aseptic processing before completing the validation of the supportive processes and systems raises the risk of failure unnecessarily and makes failure resolution well nigh impossible. Obviously, given the significance of human borne contamination as a risk factor, training and qualification of operators is a significant prerequisite to aseptic process validation. However, in an effort to move validation along quickly many firms do not emphasize training or even take short cuts with personnel education. Fortunately the various validations, which are required, are well documented in the literature and the practitioner should have no difficulty finding information on their execution (3).

REGULATORY AND HISTORICAL PERSPECTIVES

Aseptic processing activities are evaluated through process simulations in which a microbiological growth medium is utilized in the process in lieu of the product. The media is incubated after completion of the process to evaluate the procedures utilized. When utilized to evaluate aseptic filling, it is more narrowly defined as “a means of validating the aseptic assembly process that involves the use of a microbiological growth nutrient medium to simulate sterile product filling operations” (4). This technique was first applied in the late 1940s by Rhode, and incorporated into a World Health Organization guideline in the mid 1970s (5). In the late 1980’s, the PDA developed one of the first guides to the execution of media fills for the evaluation of aseptic processing (6). Several years afterwards the U.S. Food and Drug Administration defined its aseptic processing requirements for the first time (7). Additional guidance has been developed by other regulatory and pharmacopeial sources, which have defined the required activities (8–12). The PDA latest guidance documents provide perhaps the most comprehensive source of information on process simulation tests (13, 14). The desire to evaluate aseptic processing activities other than sterile drug filling has made for some adaptation of the classical media fill test, and for this reason the term process simulation test has come into vogue to embrace a wider range of aseptic processing activities. Process simulation tests can be defined as a means for “evaluating an aseptic process employing methods that closely approximate those used for sterile materials using an appropriate placebo material” (15). As mentioned previously, central to the evaluation of an aseptic process is the inclusion of the required interventions which must be performed. Any process

simulation that does not properly evaluate employee aseptic technique and does not fully consider the process human interface is technically invalid.

THE MECHANICS OF MEDIA FILL (PROCESS SIMULATION) EXECUTION

The conduct of aseptic processing validation ordinarily requires the use of a microbiological growth medium in lieu of the product. The PDA/PhRMA joint task force of Validation of Sterile Bulk Processes has outlined some process simulation methodologies which do not require the use of media (see later discussion on this subject), but aside from bulk applications process simulation testing has become essentially synonymous with media fill (16).

Media Sterilization

The execution of a media fill begins with the sterilization of the liquid media. This can be accomplished using either bulk sterilization of the liquid media in a large (glass or stainless steel) container or by filtration with a sterilizing grade filter. The choice of sterilization method is based on considerations of the volume of media required, growth promotion requirements, and filtration rate for the media. Provided that the media is introduced into the process at or before the point in which the production process being simulated becomes sterile, the choice of sterilization method is open. Whether the media be sterilized by filtration or by steam in bulk, there is no benefit to be gained from requiring that the sterilization method used be identical to that for the production materials. It is often suggested that a media fill test can be used to verify formulation bioburden control and process filter validation; however, this is not the case because as already pointed out the growth promoting and physical characteristics of media are far different from those of nearly all pharmaceutical preparations. Sterilization validation is established independent of the process simulation, and is the appropriate activity in which to confirm the appropriateness of the methods employed.

Manufacturing Activities

Once the sterile medium is in place the simulation can begin in which the aseptic processing steps are executed through the conclusion of the process. In many cases the simulation entails the filling of the product into its final container and explains its more commonly used name—media filling. To conclude however that media filling is all

that is required in the validation of aseptic processing ignores the many possible human interventions which can take place during the manufacturing and prefilling activities. Many sterile dosage forms require the execution of a significant number of complex aseptic manipulations after the materials become sterile. Suspensions, creams, ointments, implants, and liposome formulations are among the more common examples of processes where aseptic processing involves activities other than filling of containers. In the more ordinary production of sterile solutions there are manufacturing activities such as sampling and integrity testing of filters which can potentially expose sterile materials to contamination. Thus, a process simulation must include all of these prefilling activities in order to mimic the actions routinely performed in production of sterile materials. Understanding these additional requirements makes it evident why process simulation has come into vogue as a more appropriate description for this activity as opposed to more restrictive media filling. Evaluation of aseptic manufacturing activities can be achieved independently of the filling process using a variety of methods (17). If performed as part of an integrated activity with filling, the evaluation of the filled containers serves as verification of both aseptic manufacturing and filling practices.

The bulk production of sterile drug products such as antibiotics, corticosteroids, insulin, and certain biotechnology products requires that a number of processes be carried out under aseptic conditions. These processes can be evaluated in a manner adapted from those employed for aseptic filling processes. A joint PDA/PhRMA task force has developed the definitive guidance document on this subject (18).

Aseptic Filling

Media is filled into sterile containers using methods identical to those required for production of the sterile product. This activity has been the subject of numerous papers and several surveys of industry practice (19–25). Attention must be paid to the specifics of the aseptic filling process itself. The range of sterile dosage forms, which can be produced, encompasses variations in container type, container size, formulation, lot size, filling speed, and other aspects which should be embraced in the design of the validation program. Each of these must be given careful consideration in the definition of the program requirements and a sound rationale for the selection of the test conditions included in the validation protocol. Presented later are brief discussions of some of the issues to be addressed and some recommendations for execution. While the focus of these points is on activities during the

simulated filling of containers, many of these are relevant to both the manufacturing of sterile bulk materials and the compounding of bulk sterile formulations.

Product-Related Considerations

Type of container

Sterile products are aseptically filled into a variety of containers including glass and plastic bottles, metal and plastic tubes, ampules, and plastic bags. The variety of these containers is matched by the variety of methods required to prepare them for use in the aseptic filling process. Where a filling line is used to fill different types of containers, the differences in sterilization and handling suggest that each type should be assessed independently of the others. Attempting to identify a worst case situation when different sterilization methods, handling issues, and sealing mechanisms are employed is tenuous at best. One container substitution that is always valid is the use of a container that allows the most effective and less intrusive reading of the results. For example, clear containers of identical dimensions should always be substituted for opaque containers provided closure feeding and/or sealing are not affected.

Type of product

The process simulation should encompass the procedures used in the entire filling process. Thus, for lyophilized product, the aseptic loading of the freeze dryer should be a part of the simulation. A suspension product that utilizes a recycle loop around the filling machine would be validated using an identical set-up even though the media being filled does not require such a set-up. Similarly, the validation of a powder filling process should include a placebo material passed through the powder handling system and then filled into the container. When placebo materials are used development tests to ensure that the ratio of placebo to media does not result in a failure of the placebo/media mixture to support microbial growth are necessary. Any special filling or handling activities that are specific to the product being simulated should be a part of the media fill. It is acceptable to add additional steps, such as liquid filling, to a powder fill process to allow for direct incubation of the filled units. Such additional steps may increase the potential for contamination of the filled units in the process simulation relative to the production filling process, but their inclusion is often unavoidable and represents an additional worst case challenge to the process. In some instances, the use of filling of control units, i.e., vials filled with liquid media but not the placebo powder may be beneficial as a means of assessing these

add-on activities, which are not a routine part of the aseptic filling process (26).

In complex processes, the process simulation may be divided into steps. Provided that the steps overlap, they can cover the entire process and allow for isolation of contamination to a specific portion of the overall aseptic process. This practice is employed commonly for freeze drying, where an number of vials can be filled and sealed without transfer to the freeze dryer as a means of distinguishing between contamination derived from the aseptic filling and contamination derived from the lyophilizer loading and freeze drying process (27). Detailed advice on the more common product types can be found in PDA's most recent document of process simulation testing (28).

Filling speed

The extremes of filling speed on the line should be considered in the validation planning. The use of the slowest normal filling speed may increase the potential for contamination ingress via deposition from the surrounding environment. The use of the fastest normal speed may increase the potential for human intervention by increasing the number of routine and nonroutine line interventions. The likely impact of fill speed will depend upon personnel population, proximity of personnel to the sterile field, and number of interventions. A rationale should be developed for the process simulation strategy chose. For example, in the initial validation of a filling line, one fill might be performed at the slowest speed, and two at the highest speed. In routine evaluation of the line, the speeds would be alternated.

Container size

The size of the containers being filled is viewed in a manner similar to fill speed. The largest container (often filled at the slowest speed because of its large fill volume) often has the largest opening, so the potential for microbial entry from the environment should be the greatest for that size. At the other extreme, the smallest container (often filled at the highest speed by virtue of its lower fill volume), represents the greatest handling difficulty. Smaller containers are generally more fragile, and less stable, and thus would be more prone to breakage and jamming in the equipment. Any container that presents additional handling steps or is more prone to breakage or instability should be included in the validation program, as it may represent a greater challenge to the aseptic process than either the largest or smallest container processed on the line. As such it may represent an additional worst case to be addressed.

Closure system

One of the more common differences between products is the closure system. Closure systems are selected for compatibility with the formulation, and in some cases differences in formulation may be create differences in handling difficulty. A stopper that is more prone to clumping or jamming in the tracks of the stopper bowl will necessitate additional interventions not present with other stoppers of similar size and thus would be considered worst case situations. There are a number of specialized closure systems designed to facilitate the delivery of an aseptically filled product. As these systems have sealed interstitial spaces where product contact can occur during administration of the drug product, the simulation procedure for these product configurations should include this space and media should be allowed to contact these surfaces during the incubation.

Fill volume

The volume of media filled into the containers need not be the routine fill volume for the container. It should be of sufficient volume to contact the container-closure seal surfaces and sufficiently large to allow for easy inspection of the filled units postincubation. Despite the lower fill volume, the speed of filling should match that used for the routine filling of the product being simulated. Smaller containers should not be over-filled as sufficient air must be available in the container headspace to support the growth of aerobic organisms and problems have been encountered where the liquid media essentially fills the entire container.

Filling Process Related Considerations

Filling lines

Considering the number of permutations of container, closure system, and other product attributes that must be encompassed in a process simulation program, it should be evident that only in the simplest of situations would a single set of media fills be adequate to provide coverage of all aseptic processes performed. Where multiple lines are present in the facility, each should be considered independently. Process simulation results of one line are not predictive of results on another because the contamination rate is primarily dependent upon human performance. Even identical equipment in two clean rooms designed to the same standard will not give uniform results unless the aseptic technique of the operators is at the same level of performance.

Duration of fill

The duration of the media fill is one of the more contentious issues. In general, media fills should be sufficiently long to include all of the required interventions. Using that requirement alone, a typical media fill might be at least 3–4 h long. Ideally a media fill should utilize more units than are in the product being simulated. This approach is normally followed for all batches up to 5000 units. As the number of units in batch increases current practice is to fill at least 5000 units, and increase the number as the batch size increases. For very large batches or long the campaigns common in blow/fill/seal or isolator systems, media fills interspersed with blank units (either empty or water filled) are used to maintain operating conditions during the simulation. Where this is done, media is filled before and after all planned routine and nonroutine interventions, and conversion to media is performed after any unplanned nonroutine interventions (see following section). Media filled units interspersed with blank units has been a technique used to validate processes that may run for several days. In these cases media is generally filled at the beginning to evaluate set up and then again at the end to evaluate the ability of the process to maintain asepsis for the full length of the longest approved campaign. Filling a large number of units as may be possible on a high speed filling machine is not a substitute for a realistic simulation of the process. A high speed filler could fill 5000 or more units in less than 15 min of filling time, yet that would hardly be considered an acceptable practice.

Interventions

In virtually all aseptic processing activities, operator interventions are required to complete the process. Understanding the types of interventions required and how they are incorporated into the validation program is essential to protocol development.

Aseptic assembly: The first interventions performed are those that prepare the equipment for the aseptic process. This entails the removal of sterilized materials and equipment items from the autoclave and transfer to the location where the aseptic processing activities will be performed. This is ordinarily followed by the assembly/preparation of the equipment for the process. Aseptic assembly in which sterilized parts are removed from protective materials, installed and adjusted in preparation for the aseptic process are perhaps the most potentially invasive of all of the activities which must be performed. The operator must be meticulous in their execution of these tasks to prevent the inadvertent contamination of product contact surfaces. Strict adherence to the principles of aseptic technique described earlier is essential. These

interventions are a necessary part of every aseptic activity, and it is common to identify the first containers filled as they may be more indicative of potential problems with the aseptic assembly. For this reason, the validation program should include process simulations that include containers filled immediately after the set-up of the equipment.

Routine interventions: The execution of the aseptic process ordinarily requires a number of repetitive activities such as: product and component replenishment, weight checking, operator breaks, and environmental monitoring. Each of these is a required part of the process, and cannot be eliminated. They should be included in the process simulation and performed by the operators in a consistent fashion using defined methods and practices.

Nonroutine interventions: During the course of the aseptic filling process there may be instances where a nonroutine or corrective intervention is required. These usually occur in relation to difficulties with components or equipment aspects. Containers can break, jam in the conveyor, or fall over on a turntable. Stoppers can jam in the stopper track, clump in the bowl, or fail to seat properly. Problems with the equipment can include: weight adjustments, minor leakage, sensor failure, or rail adjustment. Each of these will require a corrective operation by the line operator to return the line to proper operation. Unlike routine interventions, these are not a required part of every process, but in order to assess their potential impact on the aseptic process the more prevalent of these should be included in every media fill. To the extent that these nonroutine interventions can be considered repetitive, i.e., weight adjustments, stopper jams, etc. their proper execution should be described in a procedure and adhered to by the operators. Nonroutine interventions may occur randomly or not at all during an aseptic filling process. To ensure that they are a part of the process simulation, they should be performed as if they were a required part of the simulation. Thus, even if the fill weights during the simulation are correct, the line should be stopped and an adjustment made to demonstrate the acceptability of the methods employed. Given the breadth of possible nonroutine interventions, which may be possible during a batch, it may not be possible to simulate all of them. The simulation protocol should address those the firm has identified as more commonly required. Firms should make a concerted effort to minimize the number and extent of these nonroutine interventions. It may be possible to reduce the need to perform them by improving component quality by tighter AQLs on incoming components, tighter controls on preparatory activities, repairs or upgrades to equipment, and similar activities. Such measures can contribute

substantially to the reliability of the process and patient safety.

New interventions: If during the conduct of a batch or a process simulation, the need for an intervention not previously evaluated in a process simulation may occur. The firm should allow for this eventuality and assess the intervention during its execution via supervisory observation. Further evaluation of the new intervention in a follow-up media fill should also be considered.

Documenting interventions: It can be beneficial to define in some detail the permitted interventions for a given aseptic process in an SOP. This practice eliminates any subjectivity regarding what is permitted, and also allows for the establishment of a defined method for performing the intervention. The SOP can be employed in training of the operators and used as guidance in both routine aseptic processing and process simulation. Documentation of routine processing and process simulation should include details on the interventions (routine and nonroutine) performed. The list of interventions required during routine filling can help to define the media fill program by establishing which are more common and should be given precedence in the process simulation. The required interventions can also be used as the initial justification for improvements to the procedures, components, and equipment used in the aseptic process. In the absence of such documentation during the process simulation, it is difficult to defend the acceptability of the intervention during routine processing. The use of video tapes as a means of both documenting interventions during media fills, and as a training tool for operators in the proper execution of an intervention is becoming more prevalent.

Environmental Considerations

Environmental monitoring

An aseptic processing activity is ordinarily supported by monitoring of the environmental air and surfaces in proximity to the process. The purpose of this monitoring is to confirm the acceptability of the environment during the process execution. There are a number of environmental sampling methodologies that are appropriate for this purpose each having particular advantages and disadvantages (29, 30). There are also a number of regulatory and pharmacopoeial references that delineate microbial levels considered acceptable for aseptic processing environments (31–34). Each of these documents has defined the microbial conditions under which aseptic processing operations should be conducted in a slightly different manner. This situation could prove problematic for those endeavoring to comply with all of

the requirements simultaneously except that in the years since the FDA's guideline on aseptic processing was published, aseptic processing capabilities have improved substantially. The microbial limits which may have once proved so daunting are now routinely observed in the majority of aseptic processing applications. Twenty years ago in this industry it was in vogue to speak of the importance of identifying trends in environmental monitoring results. It is recognized today, that trends no longer exist and that the presence of a detectable microorganism in a critical location is a rare event (35). With such stellar performance near routine, some change in the paradigms relative to the performance of environmental monitoring relative to aseptic processing are necessary:

- The sensitivity of environmental sampling systems may be insufficient to detect microorganisms in critical environments with any degree of accuracy.
- Increased sampling in a effort to detect the already low levels of microorganisms is unlikely to be successful and can actually put the product at risk by increasing personnel incursions into the sterile field.
- Equipment and components have improved in quality to the extent, that environmental monitoring may be the most invasive intervention during an aseptic process (an undesirable situation).
- The detection of contamination of any type in an environmental sample from a critical environment, sterility testing or a filled container during a process simulation has become a rare event.

With these views in mind, environmental monitoring must be viewed in a new light. The following insights may prove useful to the practitioner:

- To paraphrase the Hippocratic Oath, the first rule of environmental monitoring should be "to do no harm." Sampling in a effort to detect microorganisms should not increase the potential for contamination of sterile materials.
- No amount of sampling could ever establish the acceptability of filled containers of sterile product.
- The sampling and enumeration of microorganisms is perhaps more prone to inadvertent contamination than the aseptic process itself.
- The identification of a recoverable organism in the environment is a random event and may have no relationship to the integrity of the "sterile field," or the sterility of the goods being produced. In fact, given the presence of human operators (including the individual performing the sampling) how could one not expect to find occasional contamination?

- There are no “smoking guns,” establishing linkage between sterility test failure isolates, media fill contaminants and environmental isolates is extremely difficult.

Despite these somewhat negative perspectives, environments must still be monitored, and the levels of microorganisms controlled at levels that reconfirms the continued acceptability of the environmental conditions. Air sampling, using either active or passive sampling methods should be performed during the execution of the process. Surface sampling is best performed after the completion of the aseptic process to prevent the inadvertent contamination of product contact surfaces during the process. The vast majority of the samples taken should be devoid of contamination; however, the incidental detection of a recoverable organism from even product contact surfaces postprocess should not be cause for undue alarm. The sampling of the environment is also an aseptic process, and subject to its own flaws.

Personnel monitoring

The evaluation of microbial contamination on operating personnel is a necessary part of the overall program. Sampling should be considered from a perspective similar to that described above for environmental air and surfaces. In this context samples should be taken from hands and other gown surfaces only at the conclusion of the aseptic process. It is suggested that sampling of the operators be performed on every exit from the aseptic area. Unlike environmental air and surface samples, it is unrealistic to expect that all of these samples will be free of detectable organisms, nevertheless the individuals should be able to consistently meet the levels established for them. Individuals who demonstrate a repeated pattern of nonconformance with the expected microbial levels should be subjected to corrective measures. The actions taken could include retraining, aseptic processing reevaluation and gowning recertification (see following section). Personnel undergoing these corrective measures would be assigned duties outside the aseptic processing area until they have reestablished acceptable performance.

Personnel Considerations

Preparatory training

Some firms have adopted specialized aseptic processing exercises to evaluate and prepare personnel being introduced to aseptic processing activities for the first time. These tests can take the form of hand filling, media transfers, and other procedures designed to challenge the aseptic technique of the individual in the absence of the

mechanical equipment. Only after successful completion of the hands-on manipulations would an individual be considered for further training as an aseptic operator. Whether this type of evaluation is performed or not, it is generally accepted that new personnel should actively participate in a media fill before they would be allowed to perform those same activities during a production batch. Additional lecture and demonstration type training of personnel is also necessary in aspects of microbiology, aseptic technique, gowning, equipment operation, and of course CGMP.

Gowning certification

Personnel assigned work in aseptic processing areas are ordinarily subjected to initial and periodic certification of their ability to gown in the prescribed manner. Gowning certification includes sampling of a variety of gown surfaces in addition to those normally evaluated during routine monitoring (36). For new personnel, this might be successfully performed three times before they are permitted access to the aseptic corp. Annual or semiannual sampling reconfirms that personnel are still able to gown properly. Gowning certification is generally extended to include other individuals, i.e., supervisors, maintenance workers, housekeeping personnel who must access the aseptic area, but who do not perform any activities related directly to the sterility of the products being manufactured.

Personnel participation

Virtually all aseptic processing operations require the active participation of human operators who are required to perform important tasks during the process in a manner that avoids the contamination of sterile materials, components, and surfaces. Their success in performing these tasks is assessed in the process simulation as they perform the routine and nonroutine interventions, which comprise their participation in the aseptic process. In order to establish that each of the operators is capable of successfully performing their duties their periodic participation in a process simulation is required. Set-up and line operators should be a part of not less than one process simulation per year. Individuals such as line mechanics and environmental samplers should be managed in a similar manner. Participation requires more than mere presence in proximity to the aseptic process, it must include active execution of the interventions to which they are normally assigned. Supervisory staff and others, such as maintenance personnel who do not perform process related aseptic interventions should not be considered in the validation program.

One of the personnel concerns addressed by the FDA in its guideline on aseptic processing concerned the

maximum occupancy in the aseptic processing room (37). A simple means of accomplishing this is to designate a maximum occupancy for each room. Process simulations are then conducted at that level of staffing, and procedures are followed during routine operation in which a person must exit the room before another can enter whenever the maximum number of personnel are present in the room.

Where a firm operates on multiple shifts, the second and third shift should be included in the program as well to demonstrate the acceptability of their performance as well. Managing a large operation with large numbers of personnel, multiple filling lines and insuring that only personnel who have participated in a related media fill are allowed to perform aseptic processing can be a complex task.

Media Considerations

Media selection

The choice of a growth medium for use in the process simulation requires consideration of the organisms expected to be found in the environment, with emphasis on human derived contaminants from the operating personnel. With this in mind, the conventional choice is a general purpose medium capable of growing a wide range of common aerobic microorganisms (38). The usual choice is Soybean–Casein Digest Medium, also known as Tryptic Soy Broth, the same medium used in sterility testing. In some instances, other media might be appropriate. If filling is performed in an isolator under a total nitrogen environment, then an anaerobic medium such as Fluid Thioglycollate Medium might be more appropriate for the purposes of the simulation.

Use of anaerobic media

The sterility testing of parenteral products includes testing with both aerobic and anaerobic media. When media fills became common in industry during the mid-1970s the use of anaerobic media was considered a standard part of every aseptic processing validation program (39). Operational experience over recent years has indicated that the difficulty in establishing a truly anaerobic environment on a ordinary manned filling line are such that their execution is no longer common (40). Recognition that the predominant source of microorganisms in a clean room are personnel, the conduct of anaerobic media fills for other than special circumstances is unwarranted. Furthermore, anaerobic media fills are not required by any current regulatory body, as they also recognize that the focus of the effort should be on human borne contamination which can survive in air.

Media incubation conditions

An area of particular divergence in industry practice in the execution of media fills is that of incubation conditions (41). Cogent arguments can be made for incubation at a variety of temperatures. Some firms use only a single temperature in the range of 20–35°C. Other firms have chosen to incubate for 7 days at 20–25°C, and then move the filled containers to 30–35°C. An almost equal number have chosen to incubate for 7 days at 30–35°C, and then move the filled containers to 20–25°C. The lack of consensus suggests that the selection of incubation conditions is likely a minor concern. The suitability of the conditions employed, whatever they might be is established by the conduct of growth promotion studies (see following section). The one constant in this area is the duration of the incubation period which is almost universally set at 14 days (42).

Media growth promotion

The central issue in any discussion of appropriate media to use, the need to perform anaerobic media fills, selection of incubation conditions and the one that supports all of the decisions made in these areas, is the growth promotion studies. These establish that the medium used in the process simulation can successfully support the growth of microorganisms. Conventional practice is to test the media against a panel of organisms such as *Bacillus subtilis*, *Candida albicans*, *Pseudomonas aeruginosa*, *Staphylococcus epidermidis*, and *Aspergillus niger*. The use of one or perhaps two of the most common environmental isolates in the growth promotion studies is highly recommended as these may be the most likely to be encountered in a contaminated unit. Failures of the challenge organisms to grow voids the media fill and requires a repeat of the media fill. In media challenges where a powder is added to the media, studies demonstrating acceptable growth promotion are required (43). Process simulations using media performed in antibiotic product facilities will sometimes require the addition of inactivating enzymes to the media in order to obtain acceptable growth promotion results as even trace amounts of antibiotics can inhibit the growth of some organisms.

ACCEPTANCE CRITERIA

Over the last 20–30 years, nothing has proven more controversial in the validation of aseptic processing than the selection of a acceptance criterion to use. The first regulatory requirements for media fills was published by

WHO in the 1960s and had a criterion of 0.3%. Thus, a media fill of more than 1000 filled units would be considered acceptable if no more than three of those units were found contaminated after incubation (44). This limit lasted until the early 1980s when PDA prepared its first guidance on the validation of aseptic processing (45). The PDA document drew upon what was at that time the first survey on aseptic processing practice which had been conducted by PMA, and suggested a criterion of 0.1% of the units filled (46). This suggestion was at the time considered quite radical at the time as it seemingly raised the bar substantially. Interpretations of limit definition were made by Ronald Tetzlaff, at that time an employee of the Food and Drug Administration (47, 48). These drew upon suggestions made in PDA's second document on aseptic processing validation where a Poisson distribution was used to project the contamination over a large batch (49). FDA's first official statement on acceptance criteria for process simulations was provided in their 1987 aseptic processing guideline (50). The FDA guideline stated, "Test results should show, with a high degree of confidence, that the probability of a product becoming contaminated during aseptic processing is very low. In general, test results showing a probability of contamination of not more than one in 1000 are acceptable." With the publication of this document, PDA's 1980 limit had been echoed by a regulatory agency, and this limit remains FDA's current official position. PDA continued its work on aseptic processing through the conduct of industry surveys in 1986 and again in 1992 (51, 52). These efforts established that industry performance was continually improving and that 0.1% was almost universally accepted by industry on a global basis. The Parenteral Society (TPS) developed its first guidance on the validation of aseptic processing, and this placed greater emphasis on statistical treatment of the acceptance criteria than prior documents (53). This document profoundly influenced a ISO document that was then in preparation and a second controversy was born (54). The emphasis placed on statistics in both these documents made many uncomfortable. While mathematically correct the extension of the acceptance criterion tables to include larger numbers of filled units created an awareness of the statistical approach that had not existed previously. Inherent in the statistics, as the number of units filled in a media fill increased, the allowed number of contaminated units increased as well. While one contaminated unit in 1000 containers seemed acceptable, it is statistically equivalent to 10 contaminated units in 16,970 units. This seemed to many as an unacceptably large number of positives units in any size batch. Official EU guidance was provided for the first time in 1996 with the publication of their annex 1 on sterile

medicinal products (55). The annex suggested that, "The contamination rate should be less than 0.1% with 95% confidence level." This was provided without elaboration, thus while the limit was clearly statistical the implications of the TPS and ISO efforts were not addressed. The clearest response to the TPS and ISO statistical data treatment was developed by the PDA (56). The PDA guidance states the following: "Despite the number of units filled during a process simulation test or the number of positives allowed, the ultimate goal for the number of positives in any process simulation test should be zero. A sterile product is, after all, one that contains no viable organisms." The PDA that originally introduced the Poisson approach for evaluation of media fills, has revised its perspective, and now believes that statistical treatment of the data is invalid. The Poisson method is appropriate for the evaluation of a low incidence of a random event, which is no longer believed to be consistent with how sterile materials become contaminated during aseptic processing. When first introduced it was assumed that contamination in an aseptic process could be derived from a variety of sources, and that any statistical approach that addressed that possibility as a random event was considered appropriate. With the execution of many more media fills, substantial improvements in facilities and equipment, and an increased awareness of the human contribution to microbial contamination views have changed substantially. It is now a widely held belief that contamination in aseptic processing is the result of human derived contamination resulting from improper technique in the execution of a required intervention. Thus, there is nothing random about the contamination, its source is known and its elimination certainly more possible than ever. This PDA view represents the latest thinking relative to acceptance criteria. The tenants of PDA's latest effort are provided in Table 2.

Additional publications which have provided acceptance criteria for aseptic processing validation have been prepared by both CEN and PIC (58, 59). These have attempted to reconcile the differences between the ISO document and the PDA guidance. The essence of these documents is the following. "Ideally the contamination rate should be zero. However, currently the accepted contamination rate should be less than 0.1% with a 95% confidence level." This appears to be an effort to have it both ways, and it is unclear whether the two perspectives can really be reconciled so easily.

The most recent industry survey on aseptic processing was published by PDA in 1997 (60). It attempted to address the statistical nature of the limits as actually practiced, however the response to questions in that area are inconclusive. It did include evidence that several firms

Table 2 PDA views on aseptic processing validation acceptance criterion

The test methodology must simulate the process as closely as possible.
Rationale for the chosen methodology and limits must be justifiable and documented.
Test methodology should be sensitive enough to confirm a low process simulation test contamination rate, and the selected limit must be routinely achievable.
Any positive unit indicates a potential problem, regardless of run size. All positives should be identified and should result in a thorough, documented investigation.
Process simulation test contamination rates approaching zero should be achievable using automated production lines in well-designed aseptic processing facilities, blow-fill- seal and form-fill-seal and in isolator-based systems.
Processes conducted in older facilities or employing considerable product handling or manual operation may not be capable of achieving near-zero contamination rates. Nevertheless, such processes must be capable of a process simulation test contamination rate not exceeding one in 1000 when 3000 units are filled.
For batch sizes smaller than 3000 units, process simulation tests should at least equal the batch size. No positives should be allowed due to the low sensitivity of small runs.
When more than 3000 units are filled, caution should be used when deciding to increase the allowable number of positives based on arithmetic extrapolation.

(From Ref. 57.)

had adopted acceptance criteria tighter than 0.1%, suggesting that another round of acceptance criterion definition might be in the offing. The most recent commentary on acceptance criteria is that provided by USP in draft chapter, 1116 (61). The USP expanded upon PDA’s 1996 position, and established ever tighter requirements, “The goal is zero contamination. In an individual run not more than one positive unit in 5000 filled units. In a series of three media fills, two of the three media fills should have no contamination present.”

Perhaps the simplest means of establishing an acceptance criteria (and perhaps to define one’s entire program) is to follow the pack, and develop a firm’s entire aseptic processing validation program based upon the latest survey information (62). What is certainly clear is that aseptic processing performance has improved substantially over the last 20 odd years and that firms should monitor their practices against their peers and regulatory expectation on a continuing basis. What was acceptable in the past is not acceptable today, and there can be little doubt that further tightening of the criteria can be expected in the future.

Technological Advances

The production of sterile products has benefited from at least two novel production methods: blow-fill-seal and isolation technology. Each of these can offer a substantial reduction in the amount of operator interaction with sterile materials. In blow-fill-seal (and the closely related form-fill-seal), the product container is created only seconds before it is filled and sealed. This has distinct advantages over more conventional filling where containers are

exposed to the manned aseptic filling environment. A number of process simulation studies have established that the blow-fill-seal method is capable of protecting the contents of the sealed container to a greater extent than a ordinary clean room (63–65). Isolation technology enjoys similar results using an entirely different approach in which personnel are removed from the operating environment (66, 67). Isolation technology, which is a direct evolution of glove boxes, places operating personnel outside a sealed (physically or via an air pressure differential) enclosure in which the aseptic process is conducted. The enclosure can be treated with a sterilizing gas which can render the interior surfaces free of microorganisms. This treatment when combined with the elimination of direct personnel presence in the aseptic environment, makes the isolator perhaps the ideal tool for sterile drug production (68).

STERILITY ASSURANCE FOR ASEPTIC PROCESSING

To this point in this effort, the validation of aseptic processing has been described as closely related to media filling or process simulation. In reality the relationship between simulation and routine production is not a direct one. A completely successful media fill program does not establish the sterility of anything other than itself. The next lot, or for that matter the previous one, may be sterile or not. The absence of contaminated units in a media fill merely demonstrate that the facility, personnel, and procedures are capable of preventing contamination in that media fill. Demonstrating that capability for routine

filling is quite a different thing, and at the present time cannot be accomplished with other than a destructive sterility test of every filled unit. Ultimately the practitioner can only infer that because media fills are successful, that similar success is also possible during routine production. There is a common misunderstanding that the 0.1% or maximum of one in 1000 units is a sterility assurance level. That is most definitely not the case, it is nothing more than a maximum allowable contamination rate during the process simulation. There is no accepted means for establishing the sterility assurance level of aseptically filled products, it might be termed the "holy grail" of sterile production. We perform media fills to demonstrate a capability, and with significant limitations we infer from that effort that we can produce sterile drug products using aseptic processing. At the present time, this is perhaps as close as we can get to the "validation of aseptic processing." Despite this most basic of constraints, media fills represent the only means of even approximating what occurs when aseptic processing is performed. Demonstrating the capability of producing sterile products will have to be sufficient for industry needs.

CONCLUSION

Demonstrating success with aseptic processing requires process simulation studies closely matching the routine production activities. As the range of sterile products manufactured by aseptic processing is quite extensive, this mandates that the practitioner be prepared to adapt the general guidance provided in this effort to their particular situation. The more closely the simulation matches the production activities, the clearer indication that success with the simulation means success in routine operation. A well founded process simulation program affords the firm confidence in their routine operation that cannot be obtained by any other means.

It is important to consider however, that at the current level of technology, particularly manned aseptic processing, uncertainty is an inherent feature. The fact that process simulation tests are merely a snapshot in time has been recognized since media fills became a standard feature of aseptic process validation in the late 1970s. Guaranteeing safety to the end user is not as simple as successful media fill tests, "good" environmental monitoring results, and successfully completed sterility tests. Even when these data appear satisfactory, uncertainty exists. Although human nature detests uncertainty, particularly in fields where numerical values are widely stated, scientific rationality requires us to recognize that

we cannot test or monitor uncertainty away. Only by thorough training, supervision and reduction of human borne contamination hazards can the likelihood of contamination be controlled. Fortunately, it appears certain from the absence of data to the contrary that aseptically produced health care products are very safe when produced in accordance with current industry standards. Certainly as the industry process capabilities continue to evolve our products will become safer still, and perhaps someday the uncertainty associated with aseptic processing will be so low that we can consider these products truly sterile.

ANIMALS IN DRUG DEVELOPMENT

Farrel L. Fort

TAP Pharmaceutical Products, Inc., Lake Forest, Illinois, U.S.A.

ANIMALS IN DRUG DEVELOPMENT

History of Animal Use in Drug Research

The use of animals in scientific investigation has been traced back to several centuries BC. For instance, the writings of Aristotle (384–322 BC) and Erasistratus (304–258 BC) indicate that they had studied the anatomy of various animals (1). Early investigations such as these were the beginning of the basic sciences that today form the foundations for new drug development.

Until the end of the last century, experiments using living animals were carried out on domestic or easily captured wild species. The choice was usually limited and based on availability. By the end of the nineteenth century, the concept of the laboratory animal had begun to emerge as an animal deliberately chosen for its inherent suitability for the purpose; it was especially bred in captivity or obtained from its environment not merely on grounds of convenience but rather for its usefulness for the particular investigation at hand (2).

Need and Rationale for Animal Use

Tests in intact animals are necessary to understand how a drug will work in the context of the myriad metabolic and homeostatic mechanisms that are active in vivo. Screening tests are commonly conducted with in vitro systems and isolated tissues or organs to identify and, in some cases, to act as a bioassay to help purify pharmacologically active agents. However, the variable processes of absorption, distribution within the organism, metabolism to either inactive or more active products, and excretion will modulate the expression of pharmacologic activity in vivo. The only way this modulation can be estimated is by studying the new drug in intact animals.

Aside from studies of pharmacologic activity, side effects of new drugs must be identified and an initial assessment made of their risk-to-benefit ratio. Again, mechanisms of action and effects on specific organs can be studied by using in vitro techniques. However, to identify unexpected adverse effects and to estimate the dosages that may be pharmacologically active without producing unwanted effects, in vivo studies must be conducted.

Extrapolation from Animal to Human

For most substances, the mechanism of action will be the same in humans and other mammals. Therefore, quantitative rather than qualitative differences in response are most common. Humans may be more sensitive to some drugs than certain laboratory animals are, but in many cases some animal species are more sensitive than humans are. For example, the mouse is most sensitive to atropine, the cat is less sensitive, and the dog and the rabbit tolerate atropine at doses 100 times higher than does the human.

Species differences in sensitivity can often be explained by differences in metabolism, including quantitative and qualitative differences in the ability to detoxify drugs and also differences in the rates of absorption, transport, distribution, and elimination of chemicals. After oral administration, absorption in laboratory animals is generally considered to be similar to that in humans, although there are quantitative differences for some compounds. For example, species differences in the absorption and action of some compounds are related to differences in the bacterial flora of the gastrointestinal tract. The distribution and storage of drugs are reasonably consistent among mammalian species, including humans, although plasma binding tends to be more extensive in humans than in small mammals. Urinary excretion in different animal species depends to some extent on their different diets, because diet influences urinary pH and thus the extent of ionization of compounds. Biliary excretion is quite variable from species to species and is apparently more extensive in mice and rabbits than in rats and humans. Species differences in response to drugs appear to be related mainly to rates of biotransformation, which are generally more rapid in small laboratory animals than in humans (3).

ANIMAL MODELS IN DRUG DISCOVERY

Twenty years ago, the initial screening of new compounds for pharmacologic activity was conducted using whole animals or tissues and organs isolated from animals. Today most of the initial screening for new drugs is done in vitro using the techniques of biochemistry and molecular biology. Only after a new drug candidate has been

identified and studied in vitro are studies in animals initiated. The purpose of the animal studies is to verify the pharmacologic activity of the new drug, identify any unexpected pharmacologic activity, and develop an initial data base on the action of the drug in vivo.

An ideal approach would be to have an in vivo screening program designed to allow for the detection of unique profiles of activity or combinations of activities. Therefore, in addition to a set of initial screening models, relevant secondary tests would be conducted to generate additional information on specificity, mechanism of action, and possible side effects.

A complete in vivo pharmacology screening program would include models for the detection of the major therapeutic classes of compounds shown in Table 1.

The following sections describe some representative models currently in use in screening for new

pharmacological compounds. Descriptions of most of these models were derived with permission from standard operating procedures of the former Pharmakon Laboratories, Waverly, PA 18471. Many other models, as well as variations on the models to be described, are available (4–6).

CNS

A convenient test for initial screening of compounds for CNS activity would be the *neuropharmacologic profile* or open field behavior test in mice or rats. In this test, animals are dosed with the compound and placed individually in an open area consisting of a square box about 2–4 feet on each side with an open top. The animals are then observed continuously for alertness, depression, spontaneous motor activity, defecation, urination, grooming behavior, ataxia, and convulsions. The animals are systematically observed to measure time of onset, peak effect, duration, and character of drug action. This kind of test can provide an initial pharmacological appraisal of chemical compounds and an estimate of acute toxicity. CNS depressants, tranquilizers, antidepressants, central and peripheral skeletal muscle relaxants, psychostimulants, analgesics, anticonvulsants, and diuretics may be detected by this test. Other classes of drugs, however, will generally not be detected.

The *Randall–Selitto assay* is a specific test for analgesia. In this test, a suspension of 20% brewer's yeast in water is injected into one hind foot of a rat. This causes an edematous condition that increases the rat's sensitivity to pain. The test compound is administered 2 h after the yeast injection, and after an additional hour, the pain thresholds of the inflamed and noninflamed paws are measured. This is done with a device, the Analgesy Meter (Ugo Basile, Milan, Italy), which exerts a force that increases at a constant rate. The rat paw is positioned on a teflon platform, and the force is applied to the volar surface with a blunt teflon cone.

The *phenylquinone writhing assay* is also a test for analgesic activity. In this test, mice are given an intraperitoneal injection of 0.25 ml of 0.02% phenylquinone in 5% ethanol. This will cause 100% of the mice to writhe within 10 min. Characteristic patterns of writhing consist of torsion of the abdomen and thorax, drawing the hind legs close to the body, and raising the heels off the floor. Complete blocking of the writhing syndrome for 10 min after the phenylquinone injection is considered a positive response.

The ability of a test compound to cause reversal of tetrabenazine-induced ptosis in mice is an indication of

Table 1 Major therapeutic classes

CNS	Sedative–hypnotic
	Anticonvulsant
	Muscle relaxant
	Anesthetic
	Analgesic (narcotic and non-narcotic)
	Anxiolytic
	Dementia/cognition
	Antidepressant
	Neuroleptic/antipsychotic
Cardiovascular	Antihypertensive
	Anti-arrhythmic
	Cardiotonic
	Antithrombic
	Anti-anginal
	Cerebrovasodilator
Metabolic	Hypolipidemic
	Hypoglycemic
	Diuretic
Immunopharmacologic	Anti-inflammatory
	Anti-edema
	Anti-allergenic
	Anti-asthmatic
	Bronchodilator
Gastrointestinal	Immunostimulant
	Anti-ulcer
	Gastrokinesis
Antimicrobial	Antisecretory
	Antibacterial (Gram positive and negative)
	Antiviral
	Antifungal
	Antitrichomal

CNS stimulant effect. Mice are dosed with test compound and then given an intraperitoneal injection of 32 mg/kg of tetrabenazine methane sulfonate. Thirty minutes after the tetrabenazine injection, the mice are graded for the degree of ptosis. Lack or partial reversal of ptosis is considered a positive response.

Inhibition of pentylenetetrazol-induced seizures is used as an indication of hypnotic, tranquilizer, or anti-convulsive activity. Mice or rats are given the test drug, and after 30 min a dose of pentylenetetrazol, which will cause 50% of the animals to convulse (CD50), is administered intramuscularly. A drug that increases the CD50 may have activity of the type mentioned above.

Cardiovascular

Spontaneously hypertensive rats can be used to screen compounds for antihypertensive effects and for effects on heart rate. The animals are dosed for one or a few days. Blood pressure and heart rate are measured by means of an inflatable cuff around the tail. Most classes of anti-hypertensives will be detected. Agents such as beta-adrenergic antagonists will be detected by decreased heart rate. Other rat models include deoxycorticosterone acetate (DOCA)-induced hypertensive, renal hypertensive (one or both renal arteries clamped), and stroke-prone spontaneously hypertensive rats. Hypertensive dogs produced by clamping one or both renal arteries may also be used to test or verify antihypertensive activity in a second species.

Because of the ease of introducing intravenous and intra-arterial catheters and measuring blood flow and blood pressure, dogs are commonly used to conduct hemodynamic studies. These studies evaluate the effect of the test compound on systolic and diastolic blood pressure, heart rate, cardiac output, dp/dt , respiration, ECG, and ventricular pressure. From these data, effects desirable for treating angina pectoris, congestive heart failure, coronary vasospasm, and myocardial infarction can be detected.

Anti-Inflammatory

Two commonly used models to detect anti-inflammatory activity are carrageenan-induced paw edema and adjuvant-induced polyarthritis in rats. The former represents an acute and the latter a chronic inflammatory process. Nonsteroidal anti-inflammatory agents inhibit the formation of carrageenan-induced paw edema. However, to detect activity in the developing and established phases of chronic inflammation, the polyarthritis model is well accepted. In both tests the measured endpoint is volume of

the hind paw. This is done by immersing the hind paw in the well of a mercury displacement plethysmograph. In the carrageenan test, 0.1 ml of a 1% suspension of carrageenan is injected into the plantar surface of one hind paw of a rat. After 1 h the test compound is administered, and after a further 3 h the volumes of both the carrageenan-treated and nontreated hindpaws are measured. The net difference between the two measurements is an indication of the amount of edema remaining after test compound treatment. The smaller the net difference, the greater the anti-inflammatory activity of the test compound. In the polyarthritis model, 0.1 ml of a sterile 0.75% suspension of finely ground *Mycobacterium tuberculosis* or *Mycobacterium butyricum* (Freund's adjuvant) in paraffin oil is injected into the hind paw as done for carrageenan. The polyarthritis disease state takes about 20 days to develop. Therefore, to test a compound for activity in the developing stages of chronic inflammation, the test compound is administered during the first 20 days after the single injection of Freund's adjuvant. To test a compound for activity against fully developed chronic inflammation, the test compound is administered for 4–10 days, starting about 20 days after the Freund's adjuvant injection. In both the carrageenan and polyarthritis models, drug effects are expressed as the percentage inhibition of paw edema in drug-treated animals compared to non-drug-treated controls.

In the *croton oil topical inflammation* test in mice, 20 μ l of a 3% solution of croton oil is applied topically to the anterior and posterior surfaces of one ear and 20 μ l of the test drug is applied to the same ear 30 min later. Inhibition of ear swelling by more than 50% relative to vehicle-treated controls measured 2 h after croton oil application indicates acute topical anti-inflammatory activity.

Immunomodulation

Inhibition of oxazolone-induced delayed-type hypersensitivity is used as an *in vivo* test for inhibition of the cellular immune response. The shaved abdominal surfaces of groups of mice are sensitized by topical application of 0.1 ml of 5% oxazolone. The test drug is given intraperitoneally an hour later and then daily for five consecutive doses. After an additional 4 days, the animals are challenged by application of 0.5 ml oxazolone to one ear. Ear thickness is measured 24 h later. A decrease in ear thickness relative to untreated controls is an indication of immunosuppression.

Inhibition of sheep red blood cell lysis by serum from sensitized mice is an indication of suppression of the humoral immune response. Groups of mice are sensitized

by the intravenous injection of 0.2 ml of a 2% sheep red blood cell suspension. The test drug or vehicle is administered intraperitoneally to groups of mice for 3 consecutive days beginning 2 h after sensitization to sheep red blood cells. Nine days after sensitization, blood samples are collected, complement-inactivated serum prepared, and serial dilutions made. Sheep red blood cells and complement are added to aliquots of the serum dilutions. The serum titer is then expressed as the reciprocal of the dilution causing complete hemolysis. A lower than normal titer may indicate immunosuppression, and a higher than normal titer may indicate immunostimulation.

Antitussive

Dogs are surgically prepared by implantation of a small iron slug in the lumen of the trachea (7). After a 2-week recovery period, the cough response of the dogs is determined in response to electromagnetic stimulation of the implanted tracheal slug. The stimulus is imposed for 3- to 5-s periods, and the total number of coughs elicited during and 30 s after stimulation is recorded. After establishing each dog's control cough response, test substances can be administered at weekly intervals and compared with the effects observed after administration of a standard antitussive agent.

Endocrine

A simple assay for antidiabetic activity is the determination of changes that occur in blood glucose levels in rats after oral administration of a test compound followed by a subcutaneous injection of glucose. Rats are fasted overnight, administered the test compound, usually by gavage, and then immediately given a subcutaneous injection of 125 mg glucose. Two hours after test compound administration, the rats are anesthetized and blood drawn for plasma glucose determination. Decreased plasma glucose relative to controls not treated with test compound is an indication of antidiabetic activity.

Antimicrobial

Many animal models use infections artificially introduced into the animal either systemically or into specific organs or tissues. The behavior of infections and the efficacy of antibiotics in eliminating those infections differ, depending on the organ or tissue involved. The type of local pathology, the penetration and pharmacokinetics of antibiotics, the local host defense system, and the clearance rates for the bacterial inocula differ among the

various organs and tissues of an animal. Therefore, to get a reliable prediction of how effective an antibiotic will be clinically it is mandatory to test new antibiotics *in vivo*. There are a great variety of such models. For descriptions of many of these, the reader is referred to a three-volume series (8).

Anticancer

New drugs suspected of having anticancer activity are tested in standard animal models in which tumors are transplanted from one generation of animals, generally mice, to the next and are thus perpetuated *in vivo*. *In vitro* tumor cell culture systems are commonly used to determine if a new drug has cytotoxic or growth-inhibiting activity. However, the *in vivo* test is considered to be a better predictor of activity in humans.

The L1210 lymphoid leukemia model is commonly used. This tumor is carried as an ascites tumor in BDF1 or CDF1 mice. Ascites fluid from carrier mice containing 100,000 cells is implanted in the test mice. Twenty-four hours later, treatment with the test drug is started. After 6 or 7 days of treatment, the numbers of survivors are determined and the animals weighed. The results are evaluated by comparing drug-treated groups to untreated ones. Drugs resulting in a greater proportion of surviving mice compared with non-drug-treated controls may have anticancer activity. Many other similar models are available (9).

ANIMALS IN DRUG SAFETY TESTING

General Principles

Before a new drug can be given to people, it must be tested in animals to determine its side effects and at what dosage those side effects will appear. This testing must be done *in vivo* because the effects of the processes of absorption, distribution, metabolism, excretion, the interactions among these processes, and the interactions among the various organs and neuroendocrine systems within the whole animal cannot be duplicated *in vitro*. To characterize the nature of the side effects to be expected from a new drug, it is usually necessary to give much higher dosages than would be given clinically and sometimes to give the drug over prolonged periods of time. This is because the dosages of drugs needed to elicit pharmacological or toxicological effects are often higher in laboratory animals than in humans, and because the side effects of drugs suitable for clinical use are usually

provoked only by exaggerated dosages. In some cases the drug may accumulate within the body or within particular organs or tissues and thus give rise to toxic manifestations. Some side effects appear only after long periods of repeated administration.

In addition to the requirement to test new drugs in animals, it is also necessary to test in more than one species of animal, because extrapolation of the results of testing in animals to humans is less than perfect. Certain species may be more sensitive or predictive than others. To ensure that the safety of a new drug has not been overpredicted and that any potential side effects have not been overlooked, it is routine practice to test new drugs for safety in at least two species. In most cases, these will be a rodent and a nonrodent species.

The variety of animal tests and the length of the studies required for a new drug depend on the nature of the drug (pharmacological or chemical class), the intended clinical use of the drug (for example, length of the usual course of treatment), and, to some extent, on the requirements of the countries in which the new drug will be registered for marketing. These factors will be discussed further in the following sections.

Acute Toxicology

In acute toxicology testing, animals are given single doses of a drug. The most common study design is to give groups of rats or mice (such as 5 per sex) single treatments over a wide range of dosages and then observe them over a period of 7–14 days for survival and for physical or behavioral signs of toxicity. In most cases a LD₅₀ (the dosage at which 50% of the animals die) will be determined; however, this is not always feasible or necessary. The acute toxicity test may be conducted for several reasons. This is the first toxicity test that will be done for a new drug, and it provides the basis for choosing dosages that will be used in subsequent toxicity studies involving repeat dosing. This test provides information regarding the effects of single large doses of a new drug. This information may be used to predict the effects of overdosing (either accidental or purposeful) in humans. The acute toxicity test is a convenient safety check on new batches of drug. Even though extensive chemical analyses are conducted on new batches of any drug, a quick test in live animals to assure that there have been no dramatic changes in acute toxicity provides a desirable level of comfort before making the new drug batch available for human use. The acute toxicity test is also a convenient method to determine any interaction between two drugs that would cause unexpected toxicity in clinical use. Thus, if a new drug will be commonly used clinically in

combination with other drugs or in patients who commonly receive certain medications, it might be prudent to test the new drug in combination with these other drugs in an acute toxicity test in order to predict such an interaction before using the new drug clinically. A positive finding in such a combination study would likely be followed up by longer-term, repeat-dosing studies.

Acute toxicity studies may be conducted by administering the drug by any of several routes (oral, intravenous, intramuscular, intraperitoneal, subcutaneous, or dermal). The route chosen usually is that intended to be used clinically. Rats and mice are generally used for acute toxicity work; however, rabbits are commonly used when the route of administration is dermal.

If a drug is to be given parenterally, acute vein and muscle irritation studies are commonly conducted in rabbits. These studies help assure that a new parenteral formulation will not cause unnecessary pain or tissue damage in people. They are also useful in developing new formulations for parenteral use with minimal potential for such effects. In a vein irritation study, groups of drug-treated and vehicle-treated rabbits are given injections via the lateral ear veins. The reason rabbits are used for this test is because the lateral ear veins are large enough, long enough, and easily visible, so as to facilitate making the injections and identifying the injected portion for subsequent sampling for histological examination. The animals are observed during the injection and at intervals (such as 2–4 h) afterward for indications of discomfort during the injection and of swelling, erythema, or tenderness of the injection site. Twenty-four hours after injection, the animals are killed, and the injection site veins are examined histologically for evidence of tissue damage or inflammation.

In a typical muscle irritation study, groups of male rabbits are given intramuscular injections of 1.0 ml of drug formulation or vehicle with a 23-gauge needle inserted vertically to a depth of about 15–20 mm into the sacrospinalis muscle. The injection site is marked by drawing a circle of ink around the site. The animals are observed during the injection and daily thereafter for 7 days for discomfort during injection and for signs of swelling, erythema, or tenderness at the injection site. On 1, 3, and 7 days after injections, blood samples are taken for measurement of creatine phosphokinase activity. Elevation of this enzyme in blood is an indication of muscle damage. Also, 1 and 7 days after injection, rabbits from each group are sacrificed and the muscle tissue surrounding the injection site taken for histological examination for evidence of tissue damage or inflammation.

Subchronic and Chronic Toxicology

Repeat-dosing toxicity studies are conducted to determine what side effects will arise from repeated administration of a drug at lower dosages than those used in acute toxicity studies and to determine safe dosages to be used in the initial human clinical trials. These studies range in duration from 1 to 2 weeks to 1 to 2 years. The length of studies required for a drug depends mainly upon the duration of treatment and the intended clinical dosing regimen. (This is discussed further under Governmental Guidelines). These studies are conducted in stages so that the results of one study can be used to design the subsequent study of longer duration. The first are usually 2 weeks in length followed by 1-month, 3-month, 6-month, and then 1-year studies. Parallel subchronic and chronic studies are almost always conducted in two species, usually the rat and dog, because there is a large historical data base for these species and they are easy to work with, relatively economical to house, and readily available from commercial vendors. However, special circumstances may dictate that other species be used. For instance, if a drug causes excessive vomiting in dogs, which are known to be particularly sensitive to such effects, then some other nonrodent species such as the monkey may have to be used. Also, if the absorption or metabolic handling of a drug in the rat or dog is found to be markedly different from that in humans such that one of these species would not be a reasonable predictor of toxicity in humans, then another species would be used.

The usual protocol for subchronic and chronic studies includes groups of animals containing equal numbers of both sexes receiving at least three dosage levels of drug plus vehicle or other control groups. These animals are observed daily for clinical signs of toxicity. Their body weights and food consumption are measured frequently. These three parameters—clinical signs, body weight, and food consumption—can be very sensitive indicators of toxicity. Complete hematology and serum chemistry profiles are determined at least at the end of the administration period and in some cases at intervals during the period of administration. Thorough physical examinations by a veterinarian or a trained technician are conducted at regular intervals. Periodic electrocardiograms are commonly recorded in studies with dogs. At the end of the period of drug administration, all the animals are subjected to a complete necropsy under the supervision of a veterinary pathologist. The tissues are then subjected to complete microscopic examination by a veterinary pathologist to detect morphologic alterations in the tissues that may have resulted from drug administration. In some cases it may be desirable to allow some

animals from the drug-treated groups to live for a period of time after the end of drug administration to determine if any drug-related changes will disappear upon withdrawal of the drug.

As mentioned, the results of the subchronic and chronic studies are used to help determine the dosage to be used in the initial human clinical trials. To do this, the lowest dosage causing no toxicity (the *no-toxic-effect dosage*) is determined for each study, and a safety factor is applied depending on the species. For instance, for rats the no-toxic-effect dosage is divided by 10 and for dogs by 6 to arrive at an estimate for the initial human dosage. These factors are derived from the observations that laboratory animals can usually tolerate higher dosages of drugs and other chemicals without exhibiting toxicity than can humans and that the differences in tolerance vary with differences in basal metabolic rate, which in turn varies with body surface area to weight ratio. This ratio varies by a factor of approximately 10 in rats and 6 in dogs relative to humans. The descriptions of toxic effects elicited in the subchronic and chronic studies allow clinicians conducting clinical trials to know which side effects to anticipate so as to protect the patient volunteers.

Reproductive Toxicology

Reproductive toxicology covers the entire process of reproduction from mating to pregnancy, birth, weaning and, sometimes, the reproductive function of subsequent generations. The species most commonly used in these studies are rats and rabbits, although in special circumstances, other species such as mice, dogs, or monkeys may be used. A series of studies is usually conducted so as to cover all the phases reproduction. Within each study, groups of animals corresponding to untreated controls and two or three drug-treated groups are used.

One type of typical study, usually conducted in rats, provides information on fertility and general reproductive performance, particularly on gonadal function, estrous cycles, mating behavior, conception rates, and early stages of gestation. This study is usually referred to as a fertility study. Mature male rats are treated with the drug for 28 days prior to mating. This period is considered to be sufficient to detect effects on male reproductive organs when used in conjunction with thorough histological evaluation of testes. This fertility study in male animals is conducted prior to large-scale (Phase III) clinical trials in men. Female rats are treated for 14 days and then mated to treated males. Daily vaginal inspections are made and the finding of sperm or a copulation plug is considered as Day 0 of pregnancy. The females are sacrificed on Day 13,

and the number of live and dead embryos, the number of implantation sites, and the number of corpora lutea on the ovaries determined. Some of the dams may be allowed to deliver normally, and the newborn pups are counted, examined, sexed, and weighed. The pups are again weighed and counted on Days 4 and 21 (weaning). From this test, preimplantation death, derived from the number of implantation sites in the uterine horns compared to the numbers of corpora lutea on the respective ovaries, postimplantation death, derived from the number of resorption sites compared to the number of implantation sites in the uterus, and the survival and growth of the offspring are determined. This study is generally conducted prior to any clinical trials involving women of childbearing potential. However, in the USA and Europe, women of childbearing potential confirmed to be nonpregnant and using effective birth control may be enrolled in Phase I and Phase II (usually small-scale) studies prior to completion of the female fertility study.

The second typical study, commonly called the teratology study, is usually conducted in two species, rats and rabbits. Rabbits are commonly used as a second species in Segment 2 studies because after the thalidomide tragedy in the early 1960s, rabbits were found to be more susceptible than were other commonly used laboratory species to the teratogenic effects of thalidomide, one of the few proven human teratogens. In the Segment 2 test, inseminated females are treated only during the organogenesis period, which for rats and mice are Days 6–15 and for rabbits are Days 6–18 of gestation. One day prior to birth, the dams are sacrificed and the fetuses delivered by cesarean section. The fetuses are weighed, sexed, and examined for gross abnormalities. The fetuses from each treatment are then randomly divided into two groups. One group is preserved in fixative for subsequent soft tissue examination. In the other group, the tissues are cleared and the skeletons stained for skeletal examination. The main endpoints in this study are numbers of live and dead fetuses, sex ratio of the fetuses, fetus weights, grossly observable abnormalities, and soft tissue and skeletal abnormalities. This test procedure was developed based on the well-established principle that the embryo is most susceptible to induction of birth defects during the organogenesis period. Previous exposure of the dam, as in the Segment 1 test, can lead to infertility or elevation of detoxification mechanisms, and thus to underestimation of the potential of a compound to cause birth defects. A separate phase of testing was developed to specifically assess the occurrence of birth defects. This study is usually completed prior to any human studies involving women of childbearing potential (proven nonpregnant and using

effective birth control) in Europe and Japan and prior to large-scale Phase III studies involving women in the USA.

In a third type of study, called the perinatal/postnatal test, pregnant females are treated during the last quarter of pregnancy and through lactation until weaning. The weanlings are necropsied to detect any internal anomalies. The purpose of this study is to determine the effects of the drug on late fetal development, labor, delivery, lactation, neonatal viability, and growth. It also assesses potential effects on neonates due to drug being excreted in the mother's milk. The endpoints for this study are the numbers of live and dead pups, the sex ratio of the pups, the numbers of surviving pups at 4 and 21 days after birth, and the growth and development of the pups. Postnatal testing of pups commonly includes developmental indices such as days on which the following events occur: balanopreputial separation in males, vaginal opening in females, eye opening, pinna unfolding, and incisor eruption. Tests for reflex development and learning and memory are also commonly included. The reproductive competence of the offspring may also be tested. The potential of a compound to induce changes in these endpoints can be masked by infertility in the fertility and general reproductive performance study, which would lead to insufficient numbers of offspring to detect a change. This study must be completed prior to applying for marketing approval.

Mutagenicity

New drugs are routinely screened for their potential to cause gene mutations and/or chromosome aberrations by *in vitro* tests. An *in vivo* test is also required by most regulatory agencies. Further mutagenicity tests in whole animals are usually conducted only if the *in vitro* tests prove inconclusive or questionably positive. A new drug showing a strong positive response in an *in vitro* mutagenicity test probably would not be developed. *In vivo* tests serve to determine whether a drug has potential to cause genetic alterations under conditions closer to those that one would obtain under clinical use. The significance of these studies to the safety of a drug is twofold. First, a drug that causes genetic damage could produce such damage in the sperm or ovaries of the patient and thus potentially cause genetic abnormalities in the children of that patient. Second, it is widely accepted that any agent capable of causing genetic damage is also likely to be a carcinogen. The most common *in vivo* tests for genetic damage are chromosome damage tests and the dominant lethal test in mice or rats.

Chromosome damage can be assessed in mice and rats by bone marrow cytogenetic analysis and by bone

marrow micronucleus assay. In both methods, bone marrow is examined after animals have been treated with either a single high dose or after several (2–4) daily doses of the drug. After the single dose, bone marrow is collected 6, 24, and 48 h after dosing for cytogenetic analysis or 24, 48, and 72 h after dosing for micronucleus determination. After the repeat dosing schedule, bone marrow is collected 6 h or 24–30 h after the last dose for cytogenetic or micronucleus assay, respectively. For cytogenetic analysis, the animals are treated with colchicine 2–3 h prior to euthanasia to block dividing bone marrow cells in metaphase, femoral bone marrow is collected and fixed, and metaphase spreads are prepared on microscope slides. After Giemsa staining, the numbers of chromosomes and their normal or abnormal appearance in metaphase spreads are determined. In the micronucleus test, femoral bone marrow smears are stained with Giemsa or a fluorescent dye such as acridine orange, and the numbers of polychromatic erythrocytes containing micronuclei are determined. Normal polychromatic erythrocytes contain no nuclei. In the process of red blood cell maturation, the nucleus is expelled just prior to the polychromatic erythrocyte stage. Micronuclei represent chromosomes or chromosome fragments that are left behind in the cell after expulsion of the nucleus.

The dominant lethal assay is used to detect mutagenic damage to male germ cells. The principle behind this assay is that theoretically there are a large number of chromosomes that, when damaged, could lead to lethality during early gestation if included in a fertilized egg. Hence, the target size relative to the genome is large for dominant lethality, and therefore the test should be a sensitive indicator of genetic damage. In this test, male animals (usually rats or mice) are treated with the drug daily for 5 days. They are then mated with separate groups of females each week for 8 weeks. The 8-week interval covers the entire spermatogenic cycle. The females are killed at midpregnancy, about 14 days after the midweek of mating. At necropsy the uteri are examined and the numbers of corpora lutea, living implantations, and dead implantations are counted. The endpoints for this assay are (1) the numbers of preimplantation losses, determined by subtracting the numbers of implants from the numbers of corpora lutei, and (2) the numbers of dead implants. Agents that cause increased numbers of preimplantation losses or dead implants compared to vehicle or historical control levels are considered positive in the dominant lethal assay. Because of the serial mating scheme, it is possible to know which stage of spermatogenesis is affected if a positive result is obtained.

Several transgenic animal models are available for mutagenicity testing *in vivo*. The most widely used are the Big BlueTM and MutaTM Mouse models. These animals have portions of the *E. coli* galactosidase operon inserted into their genome. This bacterial DNA is used as the target for mutagenicity testing when the animals are treated with test chemicals. After chemical treatment, the bacterial DNA is removed from the tissues and packaged into bacterial viral (phage) particles. The phages are used to infect bacteria growing on agar plates. The bacteria multiply to form colonies that can be counted. Because of a color reaction that can be catalyzed by the galactosidase protein, a color reaction formed in the bacterial colonies can be used to assess the presence or absence of mutations formed in the target DNA from virtually any tissue within the treated mice.

Carcinogenicity

Carcinogenicity bioassays are long-term studies in mice and rats conducted according to standard guidelines established by the National Cancer Institute (10) and the International Conference on Harmonization (11). In these studies the animals are treated repeatedly for periods of 18–24 months for mice and of 24 months for rats. Treatment is by a route consistent with the intended clinical route. The study design usually includes vehicle control and two or three drug-treated groups. The highest dosage is selected as the maximum dosage that will be tolerated by the animals. This dosage may cause minimal signs of toxicity but should cause no more than a 10% decrement in body weight gain compared with control groups and should not cause toxicity, other than that related to a neoplastic response, that would be predicted to shorten the animal's natural life span. This high dosage is necessary to give a maximum test of the potential of a new drug to cause cancer. The animals are examined frequently for palpable masses. At the end of the treatment period, the animals are necropsied and histologic examinations of the tissues are conducted with particular attention given to the detection and identification of tumors. Recently, transgenic strains of mice that allow detection of a carcinogenic response within 6 months of treatment rather than 2 years have become available. Examples of these are the P53^{+/-} (P53 knockout), TG.AC and the rasH2 mouse models. These animals contain deletions of genes involved in suppressing the formation of tumors. The use of these animal models is justified based upon the fact that these same genes are known to be involved in many human tumors. Thus, the mechanisms leading to enhanced tumorigenic response in these animals is known to be relevant to human tumorigenesis.

Primary Irritation Testing

If a new drug is intended to be applied to the skin or eyes, one of the first tests to be conducted would be to determine if the drug, or the formulation containing the drug, will cause irritation of the skin or eyes. Even if a drug is intended only for dermal application, eye irritation testing may also be required because of the possibility of inadvertent exposure to the eyes. For instance, an antibiotic intended for topical treatment of acne would be applied on the face, and the potential for eye contact would be considerable. These tests are usually conducted in rabbits because of their widely accepted sensitivity to dermal and ocular irritation and because of the scientific literature describing such tests in rabbits. Other species, such as guinea pigs or mice, may be used for dermal irritation studies under special circumstances.

A typical dermal irritation assay is conducted as follows. Six male albino rabbits are clipped free of hair on the back. One area of skin is left intact, whereas another is abraded in a tic-tac-toe pattern with the point of a hypodermic needle so as to incise the superficial epidermis layer without causing bleeding. The test material, 0.5 ml of liquid or 0.5 g of solid or semisolid is applied to each site under a 1 × 1 in. gauze pad. The entire trunk of the animal is wrapped with an impervious material and held in place with tape for 24 h. The patches are then removed and excessive material wiped off. The skin reactions are scored at 24 and 72 h after the initial application according to a scheme such as that listed in Table 2.

Table 2 Dermal irritation scoring system

Skin reaction	Value ^a
Erythema and eschar formation	
No erythema	0
Very slight erythema (barely perceptible)	1
Well-defined erythema	2
Moderate to severe erythema	3
Severe erythema (beet redness) to slight eschar formation (injuries in depth)	4
Edema formation	
No edema	0
Very slight edema (barely perceptible)	1
Slight edema (edges of area well defined by definite raising)	2
Moderate edema (raised approximately 1 mm)	3
Severe edema (raised more than 1 mm and extending beyond the area of exposure)	4

^aThe value recorded for each reading is the average value of the six or more animals subjected to the test.

The mean values of the six rabbits for erythema and eschar formation at 24 and 72 h for both intact and abraded skin (four values) are added. The mean values of the six rabbits for edema at 24 and 72 h (four values) are also added. The total of eight values is divided by 4 to give the primary irritation index. Values of 5 or greater are considered indicative of a positive irritant (12).

A typical ocular irritation test is conducted as follows. Six albino rabbits of the same sex are given thorough ophthalmological examinations within 24 h before use to ensure absence of preexisting ocular damage. The animals would be firmly but gently restrained. The test formulation is placed in one eye of each animal by gently pulling the lower lid away from the eyeball (conjunctival cul-de-sac) to form a cup into which the test substance is dropped. The lids are then gently held together for one second and the animal released. The other eye, remaining untreated, serves as a control. For testing liquids, 0.1 ml is used. For solid, paste, or particulate substances, the amount used must have a volume of 0.1 ml weighing not more than 100 mg. The eyes of each rabbit would be examined 24, 48, and 72 h after treatment. After the 24-h examination, the treated eyes may be rinsed with tap water or saline. At this time the eyes may also be examined with the aid of fluorescein stain. One drop of fluorescein sodium ophthalmic solution USP is dropped directly on the cornea. After flushing out the excess fluorescein with tap water or saline, injured areas of the cornea appear yellow and are best seen under ultraviolet illumination. At each examination period, the eyes of each rabbit are scored for ocular reaction according to a scheme such as that listed in Table 3.

The test may be considered positive if three or more animals exhibit positive reactions at any observation period. Equivocal tests are repeated. For humane reasons, formulations known to be corrosive or to be severely irritating in the dermal irritation test are assumed to be ocular irritants and not tested (13).

Antigenicity Testing

New drugs may undergo testing for antigenicity depending upon the chemical structure (suspected of being a sensitizer because of similarity to known sensitizers) or because of the intended use of the drug. Formulations intended for topical use are usually tested for delayed contact sensitivity. However, new drugs intended for systemic use are sometimes tested for their potential to induce anaphylaxis. These tests are commonly conducted in guinea pigs, but rats or mice are sometimes used.

Table 3 Ocular irritation scoring system

Ocular reaction	Score
Cornea	
No ulceration or opacity	0
Scattered or diffuse areas of opacity (other than slight dulling of normal luster, details of iris clearly visible)	1 ^a
Easily discernible translucent areas, details of iris slightly obscured	2
Nacreous areas, no details of iris, size of pupil barely discernible	3
Opaque cornea, iris not discernible through the opacity	4
Iris	
Normal	0
Markedly deepened rugae, congestion, swelling, moderate circumcorneal hyperemia, or injection, any of these or any combination thereof, iris still reacting to light (sluggish reaction is positive)	1 ^a
No reaction to light, hemorrhage, gross destruction (any or all of these)	2
Conjunctivae	
Blood vessels normal	0
Some blood vessels definitely hyperemic (injected)	1
Diffuse, crimson color, individual vessels not easily discernible	2 ^a
Diffuse beefy red	3
No swelling	0
Any swelling above normal (includes nictitating membranes)	1
Obvious swelling with partial eversion of lids	2 ^a
Swelling with lids about half closed	3
Swelling with lids more than half closed	4

^aReadings at these numerical values or greater indicate positive response.

Delayed contact hypersensitivity can be evaluated by several standard protocols in guinea pigs. A typical procedure is to sensitize groups of 10 guinea pigs each by injecting 0.1 ml (0.05 ml for the first injection) of a 0.1% suspension or solution of test material intradermally in the upper dorsal area three times per week for a total of 10 injections. Additional groups are similarly treated with a positive control compound such as dinitrochlorobenzene

Table 4 Dermal hypersensitivity scoring scheme

Skin reaction	Score
Erythema and eschar formation	
No erythema	0
Very slight erythema (barely perceptible)	1
Well-defined erythema	2
Moderate to severe erythema	3
Severe erythema (beet redness) to slight eschar formation (injuries in depth)	4
Edema	
No edema	0
Very slight edema (barely perceptible)	1
Slight edema (edges of area well defined by definite raising)	2
Moderate edema (raised approximately 1 mm)	3
Severe edema (raised more than 1 mm and extending beyond area of exposure)	4

and a negative control (saline). About 2 weeks after the tenth injection, the animals are challenged by intradermal injection of 0.05 ml of the respective test compound, positive control, or saline in the dorsal lumbar area. The animals are shaved at least 18 prior to each injection. At 24 and 48 h after each sensitizing and challenge injection, the area of skin around the injection site is graded for erythema and edema according to the scheme shown in Table 4.

The erythema and edema grades are recorded separately. A dermal irritation score for each sensitizing injection and the challenge injection for each animal are calculated by adding the 24-h and 48-h scores for both erythema and edema (four scores) and dividing by 4. The dermal irritation scores obtained from the initial sensitizing injection and the challenge injection for each animal are used to determine whether sensitization had been produced. When the challenge score exceeds the initial irritation score for a given animal by 1 or more, the animal is considered sensitized.

The potential of a compound to induce anaphylaxis can be evaluated in both active systemic anaphylaxis (ASA) and passive cutaneous anaphylaxis (PCA) tests in guinea pigs or rats (14, 15). In both tests, the test compounds and positive and negative control substances are injected subcutaneously or intraperitoneally three times per week to groups of 6–10 animals for a total of 6 injections. In the ASA test, the animals are challenged 2 weeks after the final sensitization injection intravenously with the respective test compound or positive or negative control and observed for signs of anaphylaxis. These would be graded as:

Negative: No anaphylactic symptoms

Mild: Restlessness, rubbing of the nose or ears, coughing, expiratory acceleration, or piloerection

Moderate: Urination, defecation, dyspnea, or ataxic gait

Severe: Convulsion followed by recovery

Fatal: Death by a fatal anaphylactic reaction

In the PCA test, serum is collected from the sensitized animals 2 weeks after the final sensitization injection. This serum is diluted with saline to a dilution of 1/8 or more and injected intradermally on the backs of previously untreated guinea pigs. Four hours later, these guinea pigs are given intravenous injections of 1.5–2.0 ml of saline containing 0.5% Evans Blue plus the respective test compound or positive or negative control. Thirty minutes after the intravenous injection, the animals are examined for the presence of blue areas of skin surrounding the earlier intradermal injections. A blue spot having a diameter of 5–10 mm is considered a positive reaction.

Governmental Requirements

Governmental regulatory agencies such as the USFDA have established guidelines describing the kind of safety tests that should be conducted in animals in order to

Table 5 Duration of repeated dose toxicity studies to support phase I and II trials in the EU and phases I, II and III trials in the United States and Japan^a

Duration of clinical trials	Minimum duration of repeated dose toxicity studies	
	Rodents	Nonrodents
Single dose	2–3 weeks ^b	2 weeks
Up to 2 weeks	2–4 weeks ^b	2 weeks
Up to 1 month	1 month	1 month
Up to 3 months	3 months	3 months
Up to 6 months	6 months	6 months ^c
6 months	6 months	Chronic ^c

^aIn Japan, if there are no Phase II clinical trials of duration equivalent to the planned Phase III trials, conducting longer duration toxicity studies should be considered, as given in Table 6.

^bIn the EU and United States, 2-week studies are the minimum duration. In Japan, 2-week nonrodent and 4-week rodent studies are needed. In the United States, as an alternative to 2-week studies, single dose toxicity studies with extended examinations can support single dose human trials.

^cData from 6 months of administration in nonrodents should be available before the initiation of clinical trials longer than 3 months. Alternatively, if applicable, data from a 9-month nonrodent study should be available before the treatment duration exceeds that which is supported by the available toxicity studies.

Table 6 Duration of repeated dose toxicity studies to support phase III trials in the EU and marketing in all regions^a

Duration of clinical trials	Minimum duration of repeated dose toxicity studies	
	Rodents	Nonrodents
Up to 2 weeks	1 month	1 month
Up to 1 month	3 months	3 months
Up to 3 months	6 months	3 months
3 months	6 months	Chronic

^aAlso reflects the marketing recommendations in the three regions except that a chronic nonrodent study is recommended for clinical use >1 month.

have a new drug approved for use in clinical trials and in order to get approval of a new drug application (NDA) for marketing. The rationale and circumstances for conducting reproductive, mutagenicity, carcinogenicity, irritation, and sensitization studies have already been mentioned. Tables 5 and 6 summarize the requirements for acute, subacute, and chronic toxicity studies for pharmaceutical products intended for use in humans. These descriptions are limited to the requirements of the United States, Japan, and Europe because these areas represent the largest pharmaceutical markets in the world today. These requirements have been developed at the International Conference on Harmonization to provide uniformity among the three regions (16). Phases I, II, and III refer to the different phases of human clinical trials. Phase I refers to the initial trials, limited to one or a few doses to determine absorption, pharmacokinetics, and an initial estimate of safety. Phase II refers to larger-scale studies to establish safety and to get an initial estimate of clinical efficacy. Phase III refers to the final, large-scale, multicenter trials aimed at establishing efficacy.

CARE OF LABORATORY ANIMALS

Proper care of laboratory animals used in research is a basic requirement to assure the validity and reproducibility of the results obtained. Animals used in drug research are subject to the strictest standards of care beginning with the animal supplier. For the most commonly used laboratory animals, these standards of care often apply for the entire life of the animal. Guidelines for proper care of research animals are provided by the Department of Health and Human Services. The American Association for the Accreditation

of Laboratory Animal Care provides the service of certifying laboratories complying with those guidelines. All reputable industrial drug development houses strive to achieve and maintain certification by the association.

Sources of Laboratory Animals

Laboratory animals for drug research in industry are virtually always obtained from reputable animal suppliers who observe strict standards of care of the animals they provide. Animals that are not properly cared for often result in lost time—and therefore lost money—in drug development.

Examples of suppliers of laboratory animals are listed below.

Charles River Labs

Governmental Guidelines

The Animal Welfare Act enacted in 1966 (Public Law 89-544) and amended in 1970 (Public Law 91-579) and 1976 (Public Law 94-279) contains provisions to ensure that animals intended for use in research receive humane care and treatment. Implementing rules and regulations are published in the Code of Federal Regulations (CFR), Title 9 (Animals and Animal Products), Subchapter A-Animal Welfare, Parts 1, 2, and 3.

The U.S. Department of Health and Human Services publishes the *Guide for the Care and Use of Laboratory Animals*, Publication No. (NIH) 78-23. This was prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animal Resources of the National Research Council. The “guide” contains recommendations regarding housing, sanitation, husbandry, veterinary care, personnel qualifications, personal hygiene, occupational health, and physical plant.

The National Institutes of Health (NIH) requires that grantees and contractors using live, vertebrate animals in projects supported by NIH follow the guidelines prescribed in the guide. The Public Health Service further requires that grant-seeking institutions either be accredited by the American Association for Accreditation of Laboratory Animal Care (see later) or have an institutional committee that reviews its animal facilities and practices for compliance with the guide.

American Association for Accreditation of Laboratory Animal Care (AAALAC)

AAALAC is a nonprofit corporation directed by representatives of 24 scientific and professional organizations that are members of the corporation. It was organized in 1965 to conduct a voluntary program for the accreditation of laboratory animal care facilities and programs. AAALAC encourages optimal care for laboratory animals by providing a mechanism for peer evaluation of animal care programs by the scientific community. Humane treatment of laboratory animals, protection of personnel from hazards associated with the use of animals, and control of variables that could affect animal research adversely are among the principal objectives of the accreditation program. Animal care facilities of applicant institutions are visited and a thoroughly evaluated by two experts in laboratory animal science, who submit a detailed report to the Council on Accreditation. Following the standard listed in the *Guide for the Care and Use of Laboratory*

Animals, the Council determines whether AAALAC accreditation should be granted. Accredited facilities submit annual reports on the status of their animal facilities to AAALAC, and site visits to accredited facilities are conducted at least every 3 years. These annual reports and site visits determine whether accreditation will be continued. Full accreditation by AAALAC is accepted by the NIH as assurance that the animal facilities are evaluated in accordance with their policy on laboratory animals.

ANALYSIS OF BIOLOGICAL FLUIDS

Stephen G. Schulman

Judith A. Davis

Gayle A. Brazeau

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Biomedical drug analysis has been important for many years and has become the cornerstone for the development and formulation of new chemical entities (1). However, escalating interest, most recently as a component of patient care, has launched drug assay to the forefront of applied analytical chemistry (2–6). The topic covered herein is the accurate assessment of the concentration of a known drug, or of a particular metabolite of a known drug, in biological material such as blood or urine or tissue fluid. These techniques have also become critical in the new areas of forensic and clinical toxicology (7). The strategy is inextricably linked to knowledge of the metabolism and pharmacokinetics of the drug in question (8–13), because knowledge of metabolism governs the techniques used to ensure specificity and selectivity. The pharmacokinetic properties of the governed drug, in turn, determine the detection limits that are required.

Drugs and their metabolites are found in complex biologic matrices such as blood, urine, saliva, cerebrospinal fluid (CSF) and solid tissues. In many cases, the concentrations to be measured are in the microgram to nanogram or picogram levels. These matrices normally contain large amounts of endogenous compounds. Such compounds can interfere in the chemical and physical analytical methods used to detect and determine the materials of pharmacological interest. Consequently, unless some ultraspecific method of analysis is available for the substance of interest, physical separation of that substance from other interfering substances is usually necessary before quantitative determination can be achieved. To this end, most drug analyses must involve a separation step and a detection step. The separation step removes the drug from the biologic matrix. This separation can employ columns, solid phase extraction, solvent extraction, or a simple deproteinization of plasma with a liquid chromatography solvent such as acetonitrile. In more recent years, supercritical fluid extraction has been found to be useful for the extraction of low to moderately polar compounds. The requirements in any particular case

depend on the characteristics of the matrix, the drug, and the drug metabolites. The concentration range of the drug is also obviously important, as it will determine the methods selected for the separation and analytical procedures.

CHEMICAL BASIS FOR DRUG AND METABOLITE EXTRACTION

Many drugs are more lipophilic than the constituents of the matrices in which the compound needs to be separated from in the analyte of interest. This is the basis of Brodie's principle, which uses the least polar solvent that adequately extracts the drug from the biologic matrix (2). However, in contrast, most drug metabolites are more polar than their precursors, so that simple differential solvent extraction systems can be used to separate drugs and their metabolites. For example, nitroglycerin can be quantitatively removed from plasma by extraction into heptane, hexane, or pentane. However, its metabolites, glycerol-dinitrate and glycerol-mononitrate, are not extractable into these solvents.

Sometimes drugs and their metabolites are extractable into the same solvents. For example, chlorpromazine, demonomethylchlorpromazine, dedimethylchlorpromazine, and chlorpromazine sulfoxide are extractable into heptane (11). However, adjustment of the pH of the aqueous medium to various values between 4 and 11 permits selective extraction of one or another of the compounds. An example of the application of this principle is that chlorpromazine analysis utilizes a pH 4.6 backwash, which leaves most of the chlorpromazine in the heptane and all of the metabolites in the aqueous medium and permits a specific chlorpromazine assay (Fig. 1).

An important step forward in drug detection analysis utilizes techniques as the Bratton–Marshall approach in the sulfadimidine assay. This drug is converted to an azo dye in the Bratton–Marshall assay. However, the acetyl metabolite, if it is to be assayed, requires hydrolysis back to sulfadimidine and application of a different assay

Fig. 1 Dependence of extraction of chlorpromazine and three of its model metabolites into heptane containing 1.5% isoamyl alcohol on pH. The graph shows the percentage remaining in the aqueous solutions when equilibrated with equal volumes of the solvent mixture. (From Ref. 11.)

calculation. Unfortunately, the necessary hydrolysis conditions cause some decomposition of the unmetabolized drug, which leads to analytical errors (12). These errors, however, can be overcome with liquid chromatography approaches.

While analytical derivatizations are an effective way for extracting compounds, these often require additional steps in the analytical procedure and can introduce side products that may interfere with the analysis. Solid phase extraction has provided an alternative method to this process. The advantage of solid phase extraction is that the reagents, derivatives, and side products are maintained on the solid phase. As needed, these derivatives and side products can be selectively eluted after the desired derivative has been formed on the column. In addition, this method can eliminate potential problems associated with emulsion formulation that may occur with liquid-liquid extraction of compounds from the biological matrix. Finally, solid phase extraction is easily amenable to automation with other analytical detection methods such as gas and liquid chromatography. The phases used in solid phase extraction are the standard ones employed in other extraction methods (14).

Supercritical fluid extraction is an alternative method for the extraction of low to moderately polar compounds. This method involves the use of super- and subcritical carbon dioxide for the extraction of compounds from various matrices. An advantage of this method is that it reduces the number of hazardous or expensive chemical solvents during the extraction procedures. In recent studies (15), supercritical fluids have been suggested to be a

powerful alternative to other extraction methods. The use of supercritical fluid extraction for isolating drugs from various dosage forms and biological matrixes has been reported for fluconazole, benzodiazepines, acyclovir, and morphine. The use of superfluid extraction can result in reduced sample handling, protection from conditions that can cause degradation, such as light, heat or oxygen, high loadability of samples, ability to conduct trace analysis, and a greater assurance against undesired chemical reactions during the extraction procedure. While carbon dioxide is the most commonly used agent for supercritical fluid extraction, its nonpolar characteristics may limit its usefulness. To offset this limitation, polar organic solvents have been added to aid in the extraction efficiencies. There are several considerations that must be taken into consideration when using supercritical fluid extraction methods. While the solubility of the analyte in the supercritical fluid is important, it does not always ensure extractability. It is important to consider the location of the analyte in the matrix, as the interaction of the analyte with the active sites of the matrix must be disrupted for extractability. As such, this might require a longer extraction time, higher extraction pressure, higher extraction temperature, and a higher concentration of a modifier. Recovery is best assessed in terms of the recovery from native samples rather than from spiked samples.

During the last 25 years, gas chromatography and, even more so, liquid chromatography and liquid chromatography-mass spectrometry have become selective detection steps of choice, such that nonspecific extractions are satisfactory, with specificity introduced by the chromatographic column and quantitative detection achieved with the chromatography detector. There is now a vast literature on chromatographic drug assays, with a seemingly endless supply of separation data. Many separations involve derivatization steps following conventional chromatography work-up principles.

In the last 10 years, developments in biomedical drug analysis have mostly involved gas or high-pressure liquid chromatography, the latter using ultraviolet (UV) or visible light absorption or emission, or electrochemical oxidation or reduction as a means of detection or immunoanalysis. The introduction of liquid chromatography-mass spectrometry is quickly becoming the gold standard method due to the fact that these methods are specific, sensitive, precise, and fast. These approaches probably account for more than 90% of methods currently in use. Both chromatographic and immunoassay approaches have their advantages and disadvantages. For example, chromatography prior to detection can be time-consuming. Immunoanalysis that relies on high specificity of mammalian antibodies for specific molecules

for which they are tailored often obviates the need for separation steps.

CHROMATOGRAPHY

Chromatography is characterized by a mobile phase that moves through an open bed or a column with a stationary phase. The components of mixtures brought into the chromatographic system are separated because of their different relative affinities for the mobile and stationary phases. Solutes with a low affinity migrate with greater velocity through the system (column or bed) than components with a high affinity for the stationary phase. The migration rates depend on the structures of the solute molecules, the compositions of the stationary and mobile phases, and environmental factors, such as the temperature.

Chromatographic systems can be classified according to whether the mobile phase is a gas or a liquid, hence the distinction between gas chromatography (GC) and liquid chromatography (LC). The stationary phase can be a liquid or a solid. Frequently applied systems are gas–liquid chromatography (GLC), liquid–liquid chromatography (LLC), and liquid–solid chromatography (LSC). In paper chromatography (PC), paper is used as a support for the (liquid) stationary phase. In thin-layer chromatography (TLC), an adsorbent layer, such as silica gel, is fixed to a suitable, inert plate, such as glass; the adsorbent can function either as the stationary phase or as a support for a liquid stationary phase. In column chromatography (CC) the system is closed—the stationary phase is contained in a glass or metal column through which the mobile phase moves.

The great success of chromatography is due largely to the development of chromatographic systems with a very high degree of separation power and extremely sensitive detectors.

Gas–Liquid Chromatography (GLC)

GLC is a separation process used for analysis of volatile substances and some nonvolatile substances that can be made volatile by chemical derivatization. Historically, it was the first chromatographic method applied to trace analysis in biologic matrices. The sample to be analyzed is volatilized by flash evaporation and moved, in a relatively inert carrier gas, along a column that contains a liquid stationary phase coated onto an inert, solid support. Due to the variety of differential affinities, the various analytes in the sample have for the mobile and stationary phases, separation occurs and some components are eluted from

the column before others. Each analyte is detected as it emerges from the column by a detector that operates as a transducer.

Only in relatively few instances can a biologic sample be injected directly into a gas chromatograph. Ordinarily, some preliminary purification must be accomplished. Depending on the compound to be analyzed, the purification procedure may be simple or rigorous. Analysis of steroids requires multiple extractions with solvents, but some methods for the determination of blood alcohol allow direct injection of whole blood into the gas chromatograph. The sample preparation depends on the number of compounds in the unknown, their concentrations, the presence of interfering substances, and the column material used.

After purification, this sample may require further manipulation before injection into the gas chromatograph. Some substances in a family of compounds are so similar that they cannot be well separated from one another unless they are first converted into derivatives such as silyl ethers. By converting the compounds into ethers, the molecules are made larger and are more readily separated from one another.

A suitable solvent must be used for sample injection. The solvent most frequently used in GC are acetone, alcohol, chloroform, hexane, and other volatile organic solvents. Aqueous solutions are very rarely used in gas chromatographic analysis.

The sample (about 1–15 μ) is injected from a microsyringe into the gas chromatograph through an injection port sealed with a rubber septum. The injection port is surrounded by a metal block that is heated by an independent heating unit to a temperature considerably higher than that of the column. The temperature of the injection block is determined by the boiling point of the least volatile compound in the mixture, usually about 50–100°C above the column temperature. The evaporated sample is moved through the column by an inert carrier gas, such as argon or nitrogen. The speed with which the main mass of the injected sample moves along the column depends upon the pressure of the gas flow and the temperature of the column. The column temperature is maintained by an enclosure in an oven that operates independently of the heating element for the injection port and the oven used to heat the detector chamber.

The time required for an individual component to emerge from the column is referred to as that compound's retention time under the conditions of temperature and pressure stated. Each compound has its own characteristic retention time, forming the basis for gas chromatographic separation. The separation of the various components is governed by the partition coefficient between the gas

phase in which the sample travels and the liquid phase, which is the column coating.

Columns may be constructed of packed metal or glass, or of empty or coated glass or nylon capillaries. Metal and glass columns may be straight, coiled, or U-shaped, range in length from 1 to 6 m long, and have a bore of about 0.5 cm. Capillary columns are usually of very narrow bore (0.1 cm) and about 25 m in length. The longer the column, the more efficient, in general, is the separation.

Column packing consists of two essential ingredients—the inert supporting phase and the stationary liquid phase. The solid supporting phase is usually an inert material of uniform particle size. Diatomaceous earth is a frequently used solid support, although celite, firebrick, and glass beads are also used. The particle size is important in achieving the maximum separation or efficiency. However, smaller particles inhibit the flow rate of gas due to the increased resistance of the denser medium.

The liquid phase of the column packing is actually responsible for separating the various components of the mixture. The principal characteristics of the compounds to be considered are polarity and volatility. The liquid column coating should be nonvolatile and thermostable. Its boiling point should be approximately 250–300°C higher than the optimum temperature at which the analysis will be conducted, and it should have low viscosity. High-viscosity liquids decrease column efficiency. The melting point should ensure that the coating becomes liquid at the optimum temperature of analysis.

Nonpolar column coatings include silicone oil, hydrocarbons, and esters of high molecular weight alcohols, and dibasic acids. Polyethylene glycols, polyesters, ethers, carbohydrate esters, and derivatives of ethylenediamine are widely used polar liquid phases.

Column-packing material may be purchased already prepared. In fact, columns can be purchased already packed with the desired inert and liquid phases ready for insertion into the chromatograph.

As each component in the mixture is eluted from the column, it is detected by one of several detecting devices. The signal recognized by the detector is converted into electrical energy in the electrometer. This small signal is amplified and made to drive a pen on the recorder, where it is registered as a peak.

The recorder tracing gives two different kinds of information: 1) identification of a compound by its retention time (time it takes for the peak to appear after injection of the sample); and 2) quantitation of the compound by comparison of the area under the unknown peak with the area under a standard peak corresponding to a sample of the same analyte of known concentration.

The function of the detector is to identify and quantitate the various components that have been separated by the column and that are carried through the detector by the carrier gas. Although many different types of detectors are used in GC, only a few are used in biomedical applications. All of these produce a very small electrical current that varies in proportion to the quantity of the compound in the effluent carrier gas. This small electrical current is then amplified by the electrometer to a level sufficient to drive the recorder pen. Because very small amounts of solute (in the range of 10^{-10} mol) are present in biologic analysis, the detectors used must be extremely sensitive and stable.

The thermal conductivity detector responds to all types of compounds and has a sensitivity of approximately 10^{-8} mol solute. However, it is sensitive to temperature changes as well as to changes in the flow rate of the carrier gas. In this detector, a thin filament of wire is placed at the end of the column and is heated by passing an electrical current through it. When the effluent gas passes over the wire, a temperature change occurs, which changes the resistance in the wire. When the carrier gas contains various components of the sample, a greater temperature change is caused than with the carrier gas alone, and a greater change in resistance in the wire and a greater change in the flow of current through the wire are produced. In actual practice, two detectors are used. One detector is the reference cell through which only carrier gas passes, and the other is the cell through which the carrier gas plus the vaporized sample components pass. These two detectors are placed in a balanced electrical circuit that is adjusted by various resistors with only carrier gas flowing through both detectors so that no flow of electricity occurs. When solute is in the carrier gas passing through one detector, there is a change in resistance and current flows through the electrometer. The amplified signal is then recorded as a peak on the chart.

Organic compounds ionize when burned in a hydrogen air flame. If two electrodes at a potential difference of approximately 150 V are inserted into this flame, differences in conductivity of the flame can be measured as the solutes elute from the column and are burned. This is the principle on which the flame ionization detector is based. In the usual flame detector, the column effluent is mixed with hydrogen. This mixture is fed into the flame jet of the detector. The jet is a thin-walled stainless steel tube that also acts as one electrode. The other electrode is a fine platinum wire held above the jet. The response of this detector is practically instantaneous. It is not affected as much as the thermal conductivity detector is by changes in temperature and carrier gas flow rate. It is very sensitive and can detect approximately 10^{-10} – 10^{-15} mol solute.

In the argon ionization detector, argon is used as the carrier gas. Atoms of argon are ionized by β particles from a radioactive source as they enter the detector. The ionized argon atoms collide with solute organic molecules, whereupon secondary electrons are produced, giving rise to a current proportional to the concentration of solute in the carrier gas. The current is amplified and recorded in the usual way. The secondary electrons also generate more argon ions to replace those deactivated in the collisions with solute molecules. This type of detector is relatively unaffected by variations in temperature and carrier gas flow rate. Its sensitivity is approximately the same as that of the hydrogen flame detector (i.e., 10^{-10} – 10^{-15} mol solute).

The electron capture detector has a source of low-energy ionizing radiation. The electrons that strike the solute molecules have just enough energy to penetrate the electrical field of the molecule and be captured, but not enough energy to break the molecule into ions. The original electrical signal is decreased by electron capture. Compounds that contain halogen atoms and certain polar functional groups are most easily detected by electron capture. If the compounds to be analyzed do not contain halogen atoms, they must be halogenated prior to chromatography. The detector is more sensitive to temperature fluctuations than the argon ionization detector, but is relatively insensitive to changes in carrier gas flow rate. This detector is extremely sensitive and can detect 10^{-15} – 10^{-20} mol solute.

Occasionally, as in the case of extremely complex biologic samples, GC alone does not provide sufficient specificity or sensitivity for desired analysis. In these cases, using the ultimate detector, the mass spectrometer (MS) may be advantageous. In GC–MS, the effluent gas from the chromatograph is fed directly into the vacuum chamber of the mass spectrometer, where the separated solutes it contains are ionized either by impact with a beam of electrons that have about 70 eV energy or by collision with ionized atoms or molecules of a reactant gas (chemical ionization), which itself is ionized as a result of electron impact. The ionized analyte molecules are accelerated by a strong magnetic or electric field and after traveling some distance over a curved path, are allowed to fall on a photographic plate or are collected by an ionization detector. The locations of darkened areas (analyte ion impact regions) on a photographic plate depend upon the ratio of ionic mass to charge (m/z) and, with some knowledge of the natural abundances of isotopes of the atoms that comprise the analyte molecules, can be used to identify and quantitate the analytes. In some cases, an ionization detector equipped with a time discriminator can be used to distinguish between the arrival times of the ions of various mass-to-charge ratios (time-of-flight MS) and thereby identify the various

Fig. 2 GC–MS analysis of trifluoperazine. The diagram shows traces at mass to charge ratios (m/e) of 407 and 410, at various attenuation settings ($\times 5$, $\times 10$, $\times 20$, and $\times 50$) for blank plasma, blank plasma with trifluoperazine added, and plasma of a treated patient. The method detects “endogenous” trifluoperazine (m/e 407) and deuterated trifluoperazine internal standard. (Reproduced from the *Journal of Pharmacy and Pharmacology*).

species. Current GC–MS occupies a position of great importance in pharmacological research laboratories as it makes possible the identification and structure determination of metabolites that are present in quantities too small to be detected by other means.

The application of the combined GC–MS approach is illustrated by trifluoperazine data (Fig. 2) (11). Plasma of treated patients contains trifluoperazine itself. In the assay method, a trace (less than 1% of total) of radio-labeled trifluoperazine is added to the sample. Also added is an excess of a deuterated version of trifluoperazine. The deuterated version acts as both “cold carrier” (ensuring adequate extraction of trifluoperazine) and as the mass spectrometer internal standard. The radio-labeled trifluoperazine is used to evaluate extraction. The mass spectrometer monitors at one or more of the m/z values for both “cold” original trifluoperazine and deuterated trifluoperazine (generally 407 and 410, the parent ion m/z values). Quantitation is by standard MS ratio techniques.

HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC)

Notwithstanding the great analytical successes brought about by GLC, the method does have serious limitations.

In particular, the necessity of application to volatilized, thermally stable compounds is very restrictive, as a majority of pharmaceuticals and their metabolites are charged species at intermediate pH (aliphatic amines encompass more drugs than any other chemical class). Large molecules, such as peptides, are unstable in the injection port of the gas chromatograph and are also difficult to analyze by GLC. However, liquid-liquid partition chromatography is amenable to the analysis of ionic and large molecules as heating is not necessary. LLC, moreover, has the advantage over GLC in that the chemical natures of both the mobile and stationary liquid phases affect separability and thus analytical selectivity, whereas in GLC, only the stationary phase influences separation chemically. In LLC, either the more or less polar liquid phase may be used as the mobile phase. The latter is called *normal-phase chromatography* and the former *reverse-phase chromatography*.

The principal reason why LLC did not take precedence over GLC in the early days of analytical chromatography was the time-consuming aspect of the former due to slower mass transfer in the liquid phase. Because transfer of solute molecules between mobile and stationary phase occurs by diffusion, the much higher viscosity of liquid relative to that of a gaseous mobile phase results in diffusion rates about 10^5 times slower in the liquid; that is, partition equilibrium in the column is established very slowly. Additionally, because separation efficiency increases with increasing column length and the higher viscosity of a liquid results in slower longitudinal movement than in the case of a gas, increasing the efficiency of the separation by using a longer column increases the time of analysis.

The only way to increase the rate of diffusion of solutes is to raise the temperature substantially, but this would lead to problems in thermally unstable analytes. The alternative is to reduce the distance through which the molecules diffuse. Efficient separation then requires the use of smaller particles for column packings. This apparently simple expedient has evolved into a new practice of LC that is competitive with GLC in speed and resolution of complex mixtures and applicable to many more materials than GLC (16–19). Packing materials comprised of particles as small as $5\text{ }\mu\text{m}$ are currently available. Smaller particles are extremely difficult to handle and give an almost impermeable column. To solve this problem, solid glass beads of $30\text{--}50\text{ }\mu\text{m}$ in diameter can be coated with a layer of porous material. These are called *pellicular beads*. The porous layer may serve as a solid stationary phase or be coated with a very thin layer of liquid stationary phase with an extremely large surface area.

The thin film of stationary phase, if untreated, may be rinsed away by mobile phase under the high pressures used. One method of dealing with this is chemically bonding the liquid phase to the solid support. Porous silica beads are esterified with various alcohols that form the corresponding silicate esters. These esterified, siliceous packings are not thermally stable and are subject to hydrolysis and exchange with lower alcohols. Another type of chemically bonded packing utilizes silicone polymers, which are more stable because of their 3D cross-linked structure. For charged analytes, ion-exchange resins or celluloses are often used as packing materials.

Columns packed with small particles require high inlet pressures in order to give a reasonable flow rate. Pressures of $30\text{--}300\text{ atm}$ are commonly employed in the small columns used ($2\text{--}3\text{ mm}$ in diameter) and flow rates are typically $0.5\text{--}3\text{ ml/min}$.

HPLC apparatus consists of a mobile-phase reservoir, a sample injection system, a column, a detector, and a recorder. The operation of most of these components is self-evident, and a schematic diagram of an HPLC apparatus is shown in Fig. 3.

The smaller columns and faster flow rates place rigid requirements on the detection system. Flow-through detectors with low dead volumes and high sensitivity are necessary. The dead volume within the detector should be no more than a tenth of the analyte peak volume. Because highly efficient LC columns can give peak volumes of the order of the $50\text{ }\mu\text{l}$, a detector volume of about $5\text{ }\mu\text{l}$ is desirable.

For biomedical trace analysis, three types of detectors are currently popular—the absorption photometric detector, the fluorescence detector, and the electrochemical detector. Although there are other kinds of detectors, only these have the ability to detect $10^{-9}\text{--}10^{-12}\text{ g}$ of analyte, the kind of detectability needed in biomedical analysis, especially where small amounts of drugs are concerned.

The most widely used detectors, the absorption photometric detectors, are those based on the absorbance of UV light. They are not universal in application (19), but

Fig. 3 Block diagram of a high-performance liquid chromatograph; R is the reservoir for the mobile phase, P the pump, IP the sample injection part, AC the analytical column, RC the reference column, D the detector, FC a fraction collector (for preparative work), and FM mobile-phase, flow-rate meters.

a great many substances do absorb UV radiation, including all substances having π -bonding electrons and also those with unshared (nonbonded) electrons, such as olefins, aromatics, and compounds containing C=O, C-S, -N=O, and N=N. In UV detectors, the absorbance A is directly proportional to sample concentration and obeys Beer's Law: $A = \mu Cl$ where μ is the molar absorptivity, l is the cell path length, and C is the sample concentration. UV detectors are essentially nondestructive of the sample. The short residence time of the sample in the detector flow cells, a few seconds or less, minimizes damage to compounds sensitive to UV light. Spectrophotometric detector cells of two different types have been most commonly used in commercial HPLC systems (16). In the Z-configuration type (Fig. 4), the mobile phase moves halfway along one window of the cell, travels the distance between the two windows in line with the light beam, and goes out along the other window. A split-stream or H-flow pattern (Fig. 5) is utilized in the second type of flow cell to minimize noise and drift due to possible flow

fluctuations. The mobile phase flows into the center of the optical path, is split, and goes in opposite directions. At both ends of this optical path, the mobile phase sweeps the cell windows and is recombined in an upper bore. This cell has an optical path with dimensions of about 1 mm in diameter and 10 mm in length, with an internal volume of about 10 μ l.

Two types of photometers are used in HPLC—the fixed-wavelength filter photometer and the variable-wavelength spectrophotometer. These use a low-pressure mercury arc lamp as a light source, a transmission or interference filter to isolate a narrow band of wavelengths of light with which to excite the sample, and a photodiode to detect the light transmitted through the sample.

Most commercial fixed-wavelength UV detectors take advantage of the intense line source of 254-nm radiation in the low-pressure mercury arc lamp. The high intensity of

Fig. 5 Schematic diagram of the H cell: M is the path of the mobile phase and L is the optical path.

the radiation provides excellent detectability for the small-aperture microvolume flow cells required in HPLC. Concentration of most of the radiation in a narrow-wavelength band places less demand on optical filters and enhances the linear range of the detector.

The 254 nm wavelength has a wide range of applications. Biologically important compounds, such as aromatic amino acids, proteins, enzymes, and nucleic acid constituents, absorb strongly at 254 nm. Due to its inherently high sensitivity and the broadness of most UV absorption bands, the 254 nm detector is useful for many compounds whose maximum absorption is not at 254 nm. Nevertheless, UV detectors that offer detection at either 254 or 280 nm or at both wavelengths are also available. The 280 nm detectors employ a phosphor screen to convert 254 nm mercury arc radiation to 280 nm and generally sacrifice some linear dynamic range due to the relatively large bandwidth of the phosphor emission.

In recent years, advances in pump and column technology greatly expanded the usefulness of HPLC. As chromatographers applied HPLC to increasingly complex separations, the need arose for an absorbance detector with selectable UV wavelengths to optimize sample response and discriminate against interferences and also with sub-254 nm detection capability to allow detection of compounds such as carbohydrates and fatty acids. This need led to the development of the more sophisticated variable-wavelength UV detector. These detectors use a continuum source, such as a deuterium lamp (190- to 400 nm output), and a monochromator to isolate the narrow-wavelength bands desired. Usually, one can isolate a 2- to 16 nm bandwidth centered about the nominal wavelength. The deuterium lamp-monochromator-photomultiplier tube (or diode array) system is more expensive than the mercury lamp-filter-photodiode system of a fixed-wavelength detector.

The emission of light by molecules in solution that have been excited by the absorption of UV or visible light is the basis of the fluorescence detector (20).

The fluorimeter is a very sensitive and selective detector that is applicable to many compounds, including certain metabolites, amino acids, vitamins, and many drugs excited by UV radiation. In addition, fluorescent derivatives of many nonfluorescent substances, such as steroids, can be prepared (19). HPLC fluorescence detectors are similar to normal fluorimeters. Most fluorescence detectors are filter instruments, although variable-wavelength grating fluorimeters have been developed specifically for HPLC. Filters generally pass light in a wider band than do the monochromators, and this frequently turns out to be an advantage because the detector does not need to be specifically tuned for each compound as it elutes.

Furthermore, the filter detector is much less expensive than the variable-wavelength grating detector.

At excitation wavelengths and concentration ranges where the simple absorbance fluorescence is linear with concentration, the fluorimetric detector is susceptible to the usual interferences that hinder fluorescence measurements, mainly background fluorescence and quenching.

In the operation of a fluorimeter, the light from a UV source is filtered and focused on the cell. Fluorescence is emitted by the sample in all directions so that the emitted light can be measured with the detector at right angles to or (rarely) in line with the path of exciting light (Fig. 6). The excitation wavelength is then blocked by a filter, and the intensity of the emitted energy is measured by a photocell. Almost all of the non-halogen-containing solvents that are used with the UV-absorbance detectors can be used with the fluorescence detector. Halogenated solvents, such as CH_2Cl_2 or CHCl_3 , should be used with care because they tend to "quench" or diminish fluorescence. The solvent has a strong effect on the intensity of fluorescence. For instance, quinoline is nonfluorescent in hexane but fluorescent in ethanol.

Flow cells that can be used for both fluorescence and absorption measurements have been designed. Quantitation

Fig. 6 Schematic diagram of a fluorescence detector: S is the source of exciting light. F_1 and F_2 are filters for the exciting and emitted light, respectively; M is the position of the mobile phase containing tube with respect to the excitation-emission arrangement. The path of the mobile phase is perpendicular to the plane of the page. D is the detector, and L_1 and L_2 , are the paths of the fluorescent light detected using the right angle and in-line geometries, respectively. When the in-line arrangement is employed, F_2 and D would be colinear with S, F_1 , and L_2 .

can be considerably improved by simultaneously monitoring the absorbance and fluorescence signals. Such concurrent measurement extends the linear dynamic range for the fluorescent samples. At high sample concentrations, where the absorbance at the excitation wavelength is greater than 0.01, fluorescence response becomes nonlinear. At these higher concentrations, however, the light absorbance of the sample is often measurable and linear with concentration. Fluorescence, however, is often detectable at concentrations up to 10^{-6} times lower than those where absorbance is detectable. Native fluorescence is less common than absorption of UV or visible light. In this regard, fluorescence may be thought to be more selective or less applicable in range than absorption, depending on one's point of view.

Electrochemical detectors are based upon the voltametric oxidation or reduction of separated analytes at a micro- or thin-film electrode. A number of pharmacologically active compounds that are aldehydes, ketones, or quinones (such as doxorubicin), or nitro compounds (such as nitrofurantoin) are amenable to reduction at a mercury or platinum electrode; electron-rich indole derivatives and catecholamines can be oxidized at these electrodes. An important condition that must be fulfilled for electrochemical detection to be practicable is that the mobile phase must be capable of conducting an electrical current. This makes electrochemical detection particularly useful in reversed-phase liquid chromatography, where buffered water mixed with one or more organic cosolvents is usually the mobile phase.

The selectivity inherent to electrochemical detection is derived from the differences between the oxidation or reduction half-wave potentials exhibited by different analytes. Even when two or more analytes have nearly the same half-wave potentials, complexing agents or alterations in mobile-phase composition can be used to differentiate between analytes. In order to carry out the electrochemical quantitation of an analyte, the potential difference between the working microelectrode and the reference electrode is maintained at a value that lies on the plateau of the oxidation or reduction wave (voltammogram) of the analyte of interest. The diffusion current thus measured, which is due to the oxidation or reduction of the analyte, is proportional to the area under the analyte peak eluted. In order for absolute quantitation to be effected, the diffusion current of a standard sample of the analyte must also be measured for comparison with that of the unknown sample.

Commercial electrochemical detectors whose cells are directly connectable to the postcolumn efflux of the HPLC apparatus are available from a number of manufacturers. This method of detection is comparable

in sensitivity to detection by absorption spectroscopy when the amperometric circuit is operated as a DC pulse polarograph.

Liquid Chromatography–Mass Spectrometry

Liquid chromatography–mass spectrometry (LC–MS) is quickly becoming a very common analytical method due to its selectivity and sensitivity, and the increased availability of bench top instruments at reasonable costs for research groups (7). Since the 1970s, there have been numerous ways to remove the mobile phase in order to ionize the analyte, including fast atom bombardment, as well as particle beam, thermospray, electrospray, and atmospheric-pressure chemical ionization. In recent years, the most common and universal technique appears to be LC–MS that employs electrospray and atmospheric-pressure ionization techniques. The advantage of electrospray is that it enables the determination of compounds with large masses (e.g., peptides) or those that are very polar (e.g., quaternary amines, phospholipids, etc.). The key is that these compounds must be ionizable in solution. As such, the mobile phase often includes a small quantity of a volatile acid or base. It may be necessary to add this volatile acid or base just prior to the electrospray detection process. Atmospheric-pressure ionization techniques, in contrast, are more suitable for compounds with lower molecular mass and a moderate polarity.

IMMUNOASSAY

Immunoassay methods have become increasingly important in the field of biomedical analysis (21, 22). Analyses of nanomolar and picomolar amounts of large biopolymers present in biologic matrices, unassayable by other techniques, have provided biochemists with much essential information. Additionally, diagnostic methodologies have evolved, with immunoassays becoming centrally important in the analysis of drugs, pesticides, hormones, and proteins. Their low cost and adaptability to automation, coupled with their sensitivity and specificity, have made them competitive with chromatographic methods in diagnostics.

Immunoanalytic methods are largely based upon the competitive binding that occurs between a labeled and unlabeled ligand for highly specific receptor sites on antibodies. The analysis of this competitive binding, effected by measuring some physical or chemical property associated with the label, allows the construction of a standard curve that represents a measured physical signal that is altered by changes in distribution of bound labeled

ligand as a function of the concentration of the unlabeled ligand. Unknown ligand (analyte) concentrations are extracted from this calibration curve.

Separation of the signal corresponding to either the bound or free-labeled analyte from that of the total labeled analyte population can be accomplished in two ways. The first involves physical separation of the protein (antibody) bound fraction from the free fraction of labeled analyte. This can be accomplished by a salting-out procedure, using a salt such as ammonium sulfate or a polymer such as polyethylene glycol, to precipitate the excess and analyte-complexed antibody, followed by centrifugation. Alternatively, solid phase techniques are possible, in which drug or antibody is attached to a solid surface (beads, tube wall, dip sticks, etc.) and competition between reactants in the liquid phase and the solid phase is followed by their physical separation. These techniques are known as *heterogeneous immunoassays* and are required in radioimmunoassay, where the labels employed are radioactive, usually either ^{125}I or ^3H , and there is no way to distinguish, in situ, between the radioactivities of the free and antibody-bound labeled material. Also, the majority of immunoassay methods in which the label is an enzyme, e.g., enzyme-linked immunosorbent assays (ELISA), are heterogeneous. Homogeneous immunoassays make up the second category, in which physical separation of bound from free labeled ligand is not required. Signals that are different for the bound and free-labeled ligands are obtained from the solution, which contains all the participating analytic species. The signal-producing species may be derived enzymatically when the label is an enzyme whose substrate turnover rate is reduced upon ligand-antibody association, or the label can be a fluorophore. In this case, environmental effects imposed on specific label populations can lead to signal modification.

Separation-free, homogeneous immunoassay protocols offer several advantages in comparison to heterogeneous methods. Because no separation is involved, the number of procedural steps is decreased, which decreases the time required per assay. Additionally, because the physical transfer step is avoided, potential sample loss related to this step is eliminated. Drugs with low molecular weights (amphetamines, digoxin) are commonly measured by separation-free homogeneous immunoassay protocols (23).

Most immunoassays currently employed in the biomedical field are either radioimmunoassays, enzyme immunoassays, or luminescence immunoassays (including fluorescence immunoassays [FIA] and chemiluminescence immunoassays). Although radioimmunoassay is currently the most sensitive of these (10^{-12} – 10^{-15} M concentrations are often detectable), due to the problems inherent to

dealing with radioactive materials, such as licensing, radiation hazard, short shelf-life of expensive radioisotopes, the expense of the counting equipment, and the tedium associated with heterogeneous immunoassay, it has fallen, in popularity, behind the nonisotopic methods of analysis.

In the enzyme-multiplied immunoassay techniques (EMIT), the antigen or antibody is labeled with an enzyme (e.g., isozyme, alkaline phosphatase, horseradish peroxidase, or glucose-6-phosphate dehydrogenase) instead of a radioisotope. For example, an alkaline phosphatase-labeled drug can be made to compete with an unlabeled drug for binding sites on a drug-directed antibody. When the enzyme-labeled drug is bound to the antibody, the enzyme loses its activity (ability is bound to the antibody, the enzyme loses its activity i.e., ability to hydrolyze phosphates). However, the free enzyme-labeled drug retains its enzymatic activity. If a potentially absorbing or fluorescing organic phosphate whose optical properties are altered by the condition of esterification by phosphate is put into the solution that contains enzyme-labeled drug, drug-directed antibody, and unlabeled drug, only that fraction of the labeled drug population not bound to the antibody is capable of generating the absorption of the fluorescence spectrum of the hydrolyzed phosphate. In turn, the amount of absorptiometrically or fluorimetrically measured, hydrolyzed phosphate depends upon the concentration of unlabeled drug added to the test solution, as it is this concentration that ultimately determines how much enzymic activity is released to the solution. Commercial EMIT kits based upon absorptiometric (colorimetric) estimation of enzymatically oxidized NADH to quantitate a variety of drugs have been popular for several years. The sensitivity is not especially high, with drug concentrations down to about $0.5\text{ }\mu\text{M}$ being detectable. The measurement of the light emitted by a fluorescent or chemiluminescent enzyme substrate is capable of extending the limits of detection of the analyte down to 10^{-9} – 10^{-12} M.

FIA involves the measurement of the fluorescence of a luminescent label (a fluorophore) that participates at some level of a competitive immunochemical binding system, and whose spectral properties in most homogeneous systems vary with differences in the concentrations of the analyte. Fluorescent labels are used in homogeneous and heterogeneous immunoassay systems; they may be bound to antigens, antibodies, or solid phases, or they may exist free in solution as enzyme substrates. A fluorescent label to be used in homogeneous immunoanalysis should fulfill several requirements. Since the fluorescent signal must be measured in a serum matrix, the probe should have a high fluorescence quantum yield, and the excitation and

emission maxima of the probe should occur at wavelengths longer than those of the serum. Excitation and emission spectra of dilute serum occur at 280 and 340 nm, respectively. For a fluorescent label to be useful in a serum solution, it must emit at 50 nm or more to longer wavelengths or at wavelengths greater than 400 nm.

To date, the most popular fluorescent labels for FIA have been those derived from the long-wavelength, strongly emitting xanthene dyes fluorescein isothiocyanate (FITC) and lissamine rhodamine B (RB200) (23). The isothiocyanates or isocyanates of these fluorophores can be used to label primary and secondary aliphatic amines in aqueous solutions by simple procedures. Consequently, they can be used to label antibiotics or alkylamine-substituted drug molecules. Even those drugs that do not have indigeneous alkylamino groups can often be labeled by introducing bridging groups (e.g., aminoethyl) that are amenable to coupling with the isothiocyanate or isocyanate functions.

Heterogeneous FIAs can be carried out with the aid of the same separation procedures used in radioimmunoassay. The more expedient homogeneous FIAs usually require quenching, enhancement, or shifting of the fluorescence of the label upon binding of the labeled drug to its antibody. Occasionally, a second antibody, directed at the antidrug antibody, is used in a "double-antibody" method to precipitate the bound labeled and unlabeled drug or to alter the optical properties of the label in such a way as to make the analysis more sensitive (24, 25).

Homogeneous FIAs often can be affected even when there is no obvious change in the intensity or spectral position of fluorescence of the label upon binding to the antibody. If light-polarizing polymer films are used to polarize the exciting light and analyze the fluorescence of the sample excited by polarized light, it will generally be observed that the amount of fluorescence that reaches the detector is considerably smaller in those samples where a greater amount of antibody binding is extant, all other things being equal. This is a result of the higher degree of polarized fluorescence emitted from the labels affixed to the slowly rotating antibody. The polarized emission is more efficiently attenuated by the analyzer-polarizing film than by the unpolarized light emitted by the rapidly rotating, labeled drug molecules that are not bound to macromolecules. This phenomenon forms the basis of fluorescence polarization immunoassay. The decrease in fluorescence measured with decreasing labeled drug binding occurs as a result of increasing unlabeled drug (analyte) concentration and can be used to construct a calibration curve from which the concentrations of unknown drug samples can be determined when their

polarized fluorescences are measured. Fluorescence polarization immunoassay probably accounts for most of the FIAs currently performed.

Chemiluminescence immunoassay (25, 26), a technique that has rapidly gained popularity because its sensitivity is comparable to that of radioimmunoassay, is in a sense a variation of FIA. In the 1930s, the first work on chemiluminophores was published, but it was not until the 1980s that chemiluminescence was first tried in immunoassays. Due to the increased use of automated immunoassay analyzers, chemiluminescence has become one of the most common immunoassay detection methods used in the clinical laboratory setting (27). Chemiluminescence (also called *bioluminescence* when it occurs in fireflies and some dinoflagellates, coelenterates, and fungi) is fluorescence. However, what is usually thought of as fluorescence is light emission caused by prior light absorption by the emitting molecule. This is properly termed *photofluorescence* or *photoluminescence*. Chemiluminescence occurs in the oxidation products of some highly strained, highly reduced molecules (e.g., peroxoxalate esters and amino-substituted cyclic hydrazides of phthalic acid). The oxidation of the latter results in initial products that possess such great quantities of thermal energy from the reaction that they spontaneously (without photoexcitation) become electronically excited and subsequently fluoresce as a means of achieving the state of lowest energy. The oxidations are frequently catalyzed by metal ions and occur at appreciable rates only when the precursors of the chemiluminescent species (the labels) are freely diffusible in solution (i.e., they will not generate light rapidly when bound to antibodies or perhaps prior to release in an enzymatic reaction). In this sense, they are analogous to many of the fluorescent labels. However, photofluorescence analysis entails the measurement of light emitted by a fraction of an even smaller fraction of molecules that absorb light for an instant. In chemiluminescence, it is possible to gather and integrate the light output associated with the chemiluminescent reaction over the entire course of the reaction. Consequently, very low detection limits can be attained if the luminescence efficiency of the chemiluminescent reaction is reasonably good (0.1). Unfortunately, very few chemiluminescent reactions have high luminescence efficiencies so that the choice of labels is much more restricted than in FIA. Older chemiluminophores (luminol, isoluminol, and dioxetanes) were insoluble in aqueous buffers, which complicated the labeling process. However, the new acridinium chemiluminophores incorporate a unique sulfopropyl substituent that conveys high aqueous solubility that enhances sensitivity and overall assay robustness (27). Chemiluminescence immunoassay is a

field whose popularity is on the rise, and this may inspire the discovery of new labels.

CAPILLARY ELECTROPHORESIS

Capillary electrophoresis is an exciting, new, high resolution separation technique useful for the determination of drugs and their metabolites in body fluids. The first commercial capillary electrophoresis instruments began to emerge on the market in 1988. Today approximately a dozen companies manufacture electrokinetic capillary instrumentation, with many of these fully automated, that comprise auto samplers with computerized data evaluation (28). Capillary electrophoresis involves the electrophoretic separations of minute quantities of molecules in solution according to their different velocities in an applied electrical field. The velocity of these molecules in solution is directly proportional to their charge; therefore, the more positively charged molecules are detected first (23, 29). Capillary electrophoresis is capable of separating and quantifying cations, anions, and uncharged molecules simultaneously after the injection of very small sample sizes (1 nL) that are about 1000 times smaller than typical HPLC samples (28, 30). The separation process takes place in a narrow-bore, electrolyte filled, fused silica capillary, typically 25–75 μm in diameter by 100 cm in length, with a detection window about 50 cm from the sample loading port. Samples are introduced into the capillary either by hydrostatic or electrokinetic injection, after which electro-osmotic flow acts as a pump that sucks the sample volume into the capillary. Buffers are used to maintain a constant pH in the capillaries electrophoretic solution, and may also be used to adjust the separation parameters. The capillary is filled with the buffer solution and each end of the capillary is immersed in vials that

contain the same buffer solution along with the systems driving electrodes (Fig. 7). Sample separation occurs when an electrical field (electrophoresis) is applied. The migration rate of the sample components depends on the pH of the buffer and the voltage applied. Capillary electrophoresis employs a high voltage DC (5–30 kV) electrical current to induce the electrophoretic transport and separation of the sample components. The combined action of electrophoresis and electro-osmosis transports the sample through the capillary tube to the systems detector (23, 28–31). Various UV absorbance, fluorescence, and mass spectroscopy detectors have been used in capillary electrophoresis systems. Since UV detection techniques require the presence of a relatively high drug concentration in the sample, they have not demonstrated the sensitivity to quantify drugs in biologic fluids (28, 30). Hempel reported two methods that have been tried to remedy these problems (30). Bubble cells that extend the UV light path in the capillary detection window have only slightly increased the detection sensitivity. Another technique, the Z-shaped capillary flow cell is composed of a bent capillary tube (Fig. 8) similar to the

Fig. 7 Schematic diagram of a capillary electrophoresis system.

Fig. 8 Schematic diagram of a Z-shaped capillary flow cell.

spectrophotometric Z-configuration detector cell (Fig. 4). The Z-shaped capillary flow cell allows a few millimeters of the capillary to be parallel to the source of light. This appears to have resolved some of the earlier detector problems of scattered light. Typically, the length of the detector cell path in capillary electrophoresis is about 100 times shorter than that of HPLC (30).

Several different electrophoretic separation techniques have been used to separate an array of large and small molecules. The two most useful methods for the analysis of drugs and their metabolites in biologic fluids are micellar electrokinetic capillary chromatography (MECC) and capillary zone electrophoresis (CZE) (28, 31). MECC is an electrokinetic capillary chromatography technique that utilizes surfactants (such as sodium dodecyl sulfate) in the buffer solution at sufficient concentrations to form micelles. This technique is dependent on the formation of these micelles, which will then migrate to an electrode under the influence of an applied electrical field. There are two distinct phases in this separation process—an aqueous phase and a semistationary phase. The capillary exhibits electro-osmosis where a migration of the charged micelles and a movement of the entire liquid occur concurrently. The two phases migrate at different velocities, which allows chromatographic separation of the sample (28). Electro-osmotic flow and capillary wall chemistry are critical factors in many of these separations (32). MECC is a useful technique for the separation of both charged and uncharged drugs based on their ability to partition between the micelles and the surrounding buffer. In addition, it offers the possibility of directly injecting serum or other proteinaceous fluids (28, 31). CZE is a nonchromatographic separation technique. Although CZE does not separate neutral compounds, it is probably the simplest and most common of the capillary electrophoresis separation techniques in use today (23, 28). The separation techniques utilized in CZE are based on differences in the charge/mass/ratios of the analytes with the most positively charged analytes detected first. Separation efficiencies in CZE are typically 10–100 times that of HPLC separations, with detection sensitivity at the attomole (10^{-18} mol) level or less (23).

Laser induced fluorescence (LIF) detection may be used for fluorescent analytes, such as the fluoroquinolone antibiotics that demonstrate native fluorescence when excited at 325 nm. However, at the present time, LIF has seen rather limited use due to the fact that lasers are only commercially available with a limited range of wavelengths. This method of detection is still much too expensive for routine laboratory use, which is unfortunate considering that LIF has pushed detection limits to the zeptomole level (10^{-21} mol) (23, 30). Capillary

electrophoresis is an emerging technology that offers exciting possibilities for the determination of drugs in biological fluids.

Assessment of Drug Assay Methods

Criteria for assessment include 1) blank signal, 2) specificity, 3) precision and accuracy, 4) sensitivity, and 5) cost. Quantitation is a major issue in drug assay (10). It has been said that it is better to be roughly accurate than precisely wrong. There are few, if any, unique statistical aspects of drug assay, so there is little need to consider statistical matters such as coefficients of variation, in general, in this review. Generally speaking, drug analysts prefer the mean of two estimates over single assays. Triplicates are rarely of great value. Use of single estimates is commonly dictated by the conditions of the biologic investigation; this is obviously the case when all available biologic sample is utilized in obtaining a single estimate. All reports should include data on precision and accuracy of a method in the hands of those who conducted the work, even with extensively published, validated, and applied methods.

Several special aspects of drug assay quantitation are connected with signal-to-blank ratios and with pharmacokinetic experiments in particular. First, blank plasma (in samples from untreated patients) contains materials that give positive signals for the drug of interest. These signals obviously have to be minimized (reduction of “blank”). The signals of interest typically ought to be significantly higher than the blank signals. However, the most interesting scientific conclusions often depend on the signals close to blank. In the past, signals less than three times that of the blank were not used. In fact, this rule of thumb is an oversimplification. Signals much smaller than three times blank are usable, provided they are scientifically and statistically larger than blank. Whether or not this is so depends on the precision of the estimate of the blank and the lowest calibration point. Only a thorough review of the replication characteristics of the assay method can test this adequately. Incidentally, as in all assay work, conclusions should never be drawn on the basis of signals above blank but below the lowest calibration point.

Drug analysts must be careful with sample identification and handling. For example, plasma, serum, and blood are likely to contain different concentrations of drugs. Extraction characteristics from these three matrices also vary. This has implications for standardization and data reporting. The absolute rule in setting up standards is to compare like with like. Of course, setting up standards with exactly the same mix of contaminants and drug metabolites as in the test samples is never possible, but it

can be ensured that the same matrix is used. Standards should also be subjected to the same handling conditions as those for experimental samples in regard to collection and storage, transmission by carriers between laboratories, and so forth. Some drug analysts have set up quality control schemes to test reproducibility of their methods. Control charts such as those used in clinical laboratories are obviously useful. Multicenter quality control schemes have produced some alarming and perhaps erroneous results. Drug assays can be adversely affected by a variety of nonspecific factors, such as hemolysis in sample handling, bacterial contamination of blood collection tubes that lead to enzymatic losses of drug, anticoagulant interference, centrifugation conditions, assay contaminants entering samples from syringes and tubes, and use of antioxidants that cause reversion of drug metabolites to parent drugs. Only the application of the principle of comparison of like with like can overcome these problems.

BIOABSORBABLE POLYMERS

Shalaby W. Shalaby

Poly-Med, Inc., Pendleton, South Carolina, U.S.A.

SCOPE

Addressed in this article are polymers that, because of their current and future applications, require that they interface with living tissues for predetermined periods. Obviously, the physical presence of these polymers in the biological environment must be transient, and their physicochemical properties are expected to meet the in-use requirements and allow their transport or clearance from the application site when the intended efficacy is achieved. The transport or clearance of those polymers while in contact with tissues is termed *bioabsorption*. Hence, the term *bioabsorbable polymers* is used to denote all transient polymeric materials, regardless of their chemical type, origin, and mode of clearance or absorption from the application site. Bioabsorbable polymers can be derived from naturally occurring polysaccharides and proteins, totally synthetic polymers, or combinations of natural and synthetic components, and they may be transported from the application site through the following: 1) dissolution followed by diffusion, with or without a simple ion-exchange process to achieve solubility; 2) chemical chain dissociation of insoluble materials and their conversion to small particles suitable for phagocytosis or to soluble chain fragments that may also be metabolizable; or 3) enzymatic dissociation of the insoluble polymers to soluble moieties. Major types of bioabsorbable polymers and possible modes of bioabsorption are discussed in the next section. This section also provides some technological details on bioabsorbable materials based on soluble or solubilizable chain molecules and on polymers that can be converted to soluble forms without undergoing scission of any covalent bonds. Then an important class of polymers that undergo bioabsorption through depolymerization and chain scission is discussed. This section also includes a discussion on the newly available absorbable gel-former liquids. Throughout both sections, brief discussions relevant to the application of bioabsorbable polymers address topics such as polymer processing and applications.

MAJOR TYPES OF BIOABSORBABLE POLYMERS AND POSSIBLE MODES OF BIOABSORPTION

The chemical structure of the chain molecules is the major factor that determines the mode of bioabsorption. About two decades ago, most bioabsorbable polymers were natural polymers or derivatives thereof. Scientific interest in totally synthetic bioabsorbable polymers has grown considerably since the early seventies because of their relatively low tissue reaction and because of their more predictable in vitro and in vivo properties as compared with the natural materials. Bioabsorbable polymers can be classified into three major groups: soluble, solubilizable, and depolymerizable. The structural features and possible mode of bioabsorption of these polymers are outlined as follows.

Soluble Polymers

Soluble chain molecules are usually water-soluble, natural, modified natural, or synthetic materials. These polymers are characterized by having hydrogen-bonding, polar groups that are responsible for their water-solubility and their transport in the biologic environment. The solubility of these polymers is dependent, to a great extent, upon the type of these polar groups (hydroxyl, carboxyl, amido, or amino) and the location in the chain (as part of the main chain or side groups). Molecular weight (1) and branching of the polymer chain also play a key role in determining the polymer solubility. Examples of water-soluble polymers and the type of polar groups they carry are given in Tables 1 and 2.

Some of the most important water-soluble polymers belong to the family of polysaccharides. Soluble polysaccharides were discussed in a review by Franz (2) on polysaccharides in pharmaceutical formulations. Due to their industrial importance, key characteristics and typical applications of those polysaccharides are listed in Table 3. In addition to those noted in Table 3, the oxidation of cellulose (to convert 16–24% of its primary hydroxyl groups to carboxyl groups) produces oxidized cellulose, a

Table 1 Types of polar groups in typical examples of water soluble polymers

Polar group	Natural polymers	Modified natural polymers	Synthetic polymers
–OH	Dextran and alginic acid	Hydroxyethyl cellulose and hydroxypropyl cellulose	Polyvinyl alcohol, polyhydroxyethyl methacrylate, and low-molecular-weight polyethylene oxide
–C–O–C	Dextran	Hydroxyethyl cellulose and hydroxypropyl cellulose	Polyethylene oxide and copolymers of ethylene and propylene oxide
–COOH	Alginic acid	Carboxymethyl cellulose	Polyacrylic acid
–CO–NH ₂	—	—	Polyacrylamide
–CO–NH–	—	Gelatin	Polylysine
–C–NH ₂	—	—	Polylysine

fibrous white powder. It is used as a bioabsorbable hemostatic agent. The bioabsorption may be partly attributed to solubilization through the carboxylate moieties.

Blends of different polysaccharides and plasticizers are commonly used in pharmaceutical formulations, particularly those geared for controlled release. Due to its importance, the physical compatibility of these blends was examined by a number of investigators. Sakellariou and associates (3) studied the polymer–polymer interaction in blends of ethyl cellulose with a few cellulose derivatives (hydroxypropyl methyl-cellulose, hydroxypropyl cellulose, hydropropyl methylcellulose phthalate, and cellulose acetate phthalate) and polyethylene glycol-6000. They noted that hydroxypropyl methylcellulose phthalate and cellulose acetate phthalate exhibited initial interaction and mutual dispersion owing to the presence of the phthalyl groups.

The growing interest in new or modified water-soluble polymers or combinations thereof to meet the needs of contemporary pharmaceutical technology is illustrated by a few of the recent studies outlined below. McCormick et al. (4) have relied on copolymerization as an effective means to modify water-soluble polymers, as illustrated in a recent communication. The effect of alkyl side groups on the properties of polyelectrolytes was examined earlier by Dubin and Strauss (5, 6). Pantar and Rao (7), who were also interested in developing polyacrylamide (PAAm) having enhanced dissolution rates, noted the following: 1) the rate of dissolution of this polymer increased when it is prepared in the presence of polyethylene glycols (PEG) 200 and 400; 2) heterogeneous PAAms were found to have occluded

the PEG; and 3) incorporation of PEG decreased with the increase in its molecular weight. Gelation and properties of hydrogels based on water-soluble polymers remain important areas, as stressed in a review by Ross-Murphy and McEvoy (8). The gamma ray-induced cross-linking of PAAm with a dose of over 50 kg produces hydrogels that absorb water by 1000–1500 wt% (9). Barbucci et al. (10) synthesized new polymers with amido and amino groups in the side chains and demonstrated the importance of hydrophobic interaction on the protonation of these polymers leading to their solubilization. Association of water-soluble polymers and formation of hetero-pairs by intermolecular complex formation have been the subject of early investigations and hold great promise for future research (5, 6, 11–15).

A review by Drobnik and Rypáček (16) summarized key findings and some theories on the fate of water-soluble polymers in living organisms, using a compartmentalized model to discuss the polymers' pharmacokinetics and their movement across several biologic barrier membranes in an organism. Compartments of this model are characterized by similarity in the mechanism of crossing the biologic barriers. Thus, the plasma circulation is viewed as the central and the only compartment across which the exchange of compounds between remote parts of the body may be accomplished. Intracellular exchanges were associated with a large intracellular compartment entailing all cells in the body. The authors discussed in some detail the participation of cells of the reticuloendothelial system (RES), kidney tubular epithelium, and liver hepatocytes. The lymph system and interstitium were denoted as important compartments in dealing with synthetic, water-soluble

Table 2 Structural features of typical water-soluble polymers

Name	Class of polymer or source	Solubilizing groups	Other features
Dextran (DXT)	Natural polysaccharide; a bacterial fermentation product	-C-O-C-	Substituted pyranose chain sequences
Carboxymethyl cellulose and its alkali metal salts (CMC)	Carboxyalkylated cellulose	-C-OH -C-O-CH ₂ COOH	Substituted pyranose chain sequences
Hydroxyethyl cellulose (HEC)	Ethoxylated cellulose	-C-O-C	Substituted pyranose chain sequences
Hydroxypropyl cellulose (HPC)	Propoxylated cellulose	-C-O-CH ₂ -CHCH ₃ -OH -C-O-C	Substituted pyranose chain sequences
Hydroxypropyl methylcellulose (HPMC)	Methylated HPC	Similar to HPC	Substituted pyranose chain sequences
Poly(β -hydroxyethyl methacrylate) (PHEMA)	Synthetic, by direct polymerization	-CO-O-CH ₂ CH ₂ OH	Substituted polyethylene chain
Polyvinyl alcohol (PVA)	Synthetic, hydrolysis product of polyvinylacetate	CH-OH	Substituted polyethylene chain
Polyacrylamide (PA)	Synthetic, by direct polymerization	-CONH ₂	Substituted polyethylene chain
Polyacrylic acid and its alkali metal salts (PAA)	Synthetic, by direct polymerization	-COOH, -COO-Na ⁺ and/or -COO-K ⁺	Substituted polyethylene chain
Polyvinylpyrrolidone (PVP)	Synthetic by direct polymerization	-CO-NH-	Substituted polyethylene chain
Polyethylene oxide (PEO or PEG)	Synthetic polyether, by acyclization of ethylene oxide	-CH ₂ -O-CH ₂ -	Chains carry 2 (OH) end groups, at low and moderate molecular weights
Poly(ethylene oxide- <i>b</i> -propylene oxide) (PEO-PPO)	Synthetic block copolymers of ethylene and propylene oxide	-CH ₂ -OH -CH ₂ -OCHCH ₃ -	Chains carry up to 2 (OH) end groups, depending on molecular weight
Amylose (soluble starch)	Natural, linear component of starch	-CH ₂ -O-CH ₂ -CH ₂ OH -CHCH ₃ -OH	Substituted pyranose sequences
Alginate acid and its alkali metal salts	Natural, polysaccharide from seaweed	-C-O-C -C-OH C-O-C	Substituted pyranose sequences of <i>d</i> -mannuronic acid
Polylysine	Synthetic	-C-COOH -C-OH -CO-NH- -C-NH ₂ -C-O-C-	A basic polypeptide
Hyaluronic acid	Natural polysaccharide (e.g., in rooster comb); also a bacterial fermentation product	-C-OH -C-NHCO-CH ₃ -COOH	Substituted pyranose sequences of acetyl Glucosamine and glucuronic acid

Table 3 Soluble polysaccharides: key features and typical applications

Polysaccharide	Structural features	Source and properties	Applications
β -Cyclodextrin	Based on 7 glucopyranose units; the α -form has only 6 units	Amylose derived, cyclic heptasaccharide, capable of forming inclusion complexes of drugs	Inclusion complexes with drugs to mask odor to taste
Methylcellulose	Methylated cellulose with a methoxy content of about 6 – 15%	Solutions are stable at pH 2–12 but coagulate or precipitate in presence of SO_4^{2-} , CO_3^{2-} or PO_4^{3-}	Ophthalmic and burn preparations, nose drops and ointments
Cellulose acetate phthalate	Esterified cellulose with about 20 and 35% acetate and phthalate groups, respectively	Free acid form dissolves in organic solvents and only the alkali metal salts are water soluble	Protective coating of tablets, insoluble in stomach but soluble in intestine fluids
Carboxymethyl cellulose	Usually prepared as the carboxylic salt of polycarboxymethyl ether of cellulose	Dispersion of the free acid or its sodium salt is stable at a wide pH range (2–10)	Thickening agent and tablet excipient
Acacia gum	A mixture of structurally related polysaccharides, the main one is based on β -D-galactopyranose residues	Natural plant exudates solutions are stable at pH 2–7 and display relatively low viscosity	Emulsifying or suspending agents, adhesive and binders (in tablets)
Tragacanthin	A complex mixture of polysaccharides containing some galacturonic acid residues	The soluble component of the natural (plant origin) tragacanth gum	Binder (in tablets) and demulcent
Pectin	Made of partly methoxylated 1,4-linked polygalacturonic acid	At pH 3 pectin forms a thermoreversible gel. It is extracted from citrus peel	Suspending agent, antidiarrheal formulations
Alginate acid	Linear polymer made of β -1, 4-D-mannuronic and L-glucuronic acids	Extracted from brown algae, the polymer sodium salt and not the free acid or calcium salt dissolves in water	Thickening, emulsifying, or gel-forming agent
Agar	Based primarily on galactose sequences	Extracted from red algae	Suspending or emulsifying agent, surgical lubricant, and tablet disintegrant
Galactomannans	Made primarily of a linear mannose chain with galactose side groups	Obtained from the powdered endosperm of certain seeds, guar gum	Thickening agent and tablet binder
Xanthan	Made primarily of linear glucose chain with side chains based on mannose and glucuronic acid residues	A microbial gum made by glucose fermentation, forms viscous pseudoplastic solutions	Emulsifying or suspending agent, particularly in toothpaste and ointments
Dextran	The polysaccharide chain is made primarily (based on the bacterial strain used in fermentation) of glucan units having α -1,6-linkages and fewer α -1,2- and 1,3 or 1,4-linkages to give a highly branched structure	A class of exocellular bacterial glucans, commercial dextrans have molecular weights of 40 to 110×10^3 . The low molecular wt. dextran (40,000) was reported to clear readily through the kidneys	Blood extender
Hyaluronic acid	Made of acetyl glucosamine and glucuronic acid (partially neutralized to dissolve) sequences	Obtained by the extraction of rooster comb or as a bacterial fermentation product, molecular weight ranges from 0.5 to 3×10^6	Exceptional lubricant for living tissues

(From Ref. 2.)

polymers. Ways in which water-soluble, endogenous and exogenous polymers cross compartmental barriers include transendothelial passage, transport into the lymphatic system, glomerular filtration, tubular secretion, intestinal transport, and biliary transport. In their discussion of compartmental barrier crossing, the authors indicated that water-soluble polymers cannot pass across a lipoprotein membrane by any type of diffusion process without the interruption of the membrane integrity and the development of defects in the cell surface. These defects can be caused by polyelectrolytes or a high concentration of polyethylene glycol. On the other hand, a common process by which polymers can cross a biologic membrane is invagination of the membrane, that is, the formation of a vesicle that buds inward and separates from the membrane. This process, in which the macromolecules enter the cell completely enclosed in a membrane vesicle containing some extracellular fluid, is generally termed *endocytosis*. The authors indicated that vesicle transport seems to be the only way in which synthetic polymers can overcome the lipoprotein membrane barrier. Drobnik and Rypáček (16) also

discussed the mechanism of storage in cells and elimination via the respiratory system. Although the authors stressed the role of endocytosis in transporting large molecules across biologic barriers, the passive diffusion of soluble polymers of less than 20,000 molecular weight was not excluded. Polymers addressed in this section may or may not undergo limited changes during their residence in the organism. The changes may consist of modifications that have minor effects on their mode of transport, absorption, and eventual elimination from the organism. The chain modification may be associated with hydrolytic reactions, oxidative processes, and/or conjugation (usually through esterification, acylation, or alkylation) but are not expected to introduce major changes in the chain molecular weight or solubility.

Solubilizable Polymers

The second group of bioabsorbable polymers, namely, the solubilizable macromolecules, may be viewed as derivatives of the water-soluble polymers as outlined in

Table 4 Soluble depolymerizable polymers

Name	Class of polymer of source	Solubilizing groups	Other features
Hyaluronic acid (HA) and its alkali metal salts	Natural polysaccharide from rooster comb or obtained as a fermentation product	C—O—C —C—COOH —C—NH—CO—CH ₃ —C—OH	Substituted pyranose cosequences of glucuronic acid and acetyl glucosamine
Pectin and its alkali metal salts	Natural polysaccharide from citrus fruits	—C—O—C —C—COOH —C—OH	Substituted pyranose sequences of galacturonic acid
Gelatin	A hydrolysis product of collagen (a natural polymer)	Mostly —CO—NH—	Major constituent amino acids are glycine, proline, and hydroxyproline
Protamine (as a sulfate)	Natural polymer from fish eggs	—COHN— —COHN— —NH—C—NH ₂ NH	A basic low-molecular-weight protein with arginine as a dominant amino acid constituent

Tables 2 and 3 or as a subgroup of the depolymerizable soluble polymers, which are described in Table 4. The solubilizable macromolecules can be insoluble calcium or magnesium salts of carboxylic or sulfonic acid bearing synthetic chains that undergo dissolution in the organism by cation exchange with alkalic metal salts. From this point on, the bioabsorption of these materials follows the same pattern as those noted for the water-soluble polymers. In addition, a solubilizable polymer can conceptually be a synthetic insoluble macromolecule that undergoes limited in-chain or side-chain scission to produce water-soluble, lower molecular weight fractions. For instance, a polyether-ester copolymer of polyethylene glycol diol with glycolic acid and/or an aliphatic diacid may undergo hydrolysis to a water-soluble polyethylene oxide and low molecular weight polyester fragments that undergo further hydrolysis to water-soluble monomeric species. The bioabsorbability of polymethyl cyanoacrylate may also in part be attributed to hydrolysis of the ester and/or the cyano group attached to the polyethylene main chain to create water-soluble polymeric moieties, which are transported and eliminated from the living organism earlier for intrinsically water-soluble polymers as discussed.

Depolymerizable Polymers

The third class of bioabsorbable polymers are those made of chains that undergo depolymerization to simple organic compounds in the living organism. The depolymerization may take place via an enzyme-catalyzed or chemically induced scission of the polymer chains, as in the case of collagen or polyglycolic acid, respectively. Most, if not all, the enzymatically

depolymerizable (or simply degradable) polymers are naturally occurring chains such as collagen or fermentation products, as in the case of poly- β -hydroxybutyric acid (PHB) (17). In addition, enzyme-degradable (or depolymerizable) polymers can be water-soluble (e.g., gelatin, pectin, hyaluronic acid, and protamine sulfate) or water-insoluble (e.g., collagen). A list of the water-soluble depolymerizable polymers is given in Table 4. Depending on their molecular weight, movement of the water-soluble polymers across the biologic membrane can take place by passive diffusion or endocytosis (or pinocytosis) as for low and high molecular weight chains, respectively. In most cases, however, water-soluble polymers undergo enzyme-catalyzed chain degradation to essentially monomeric species that can be metabolized further or excreted as such. The water-insoluble depolymerizable polymers are represented by three major naturally occurring polymers and derivatives thereof. The most common types of water-insoluble depolymerizable polymers are those based on natural proteins such as collagen and its derivatives (through complex formation with transition metals such as chromium ions). These are degraded by collagenase to soluble low molecular or monomeric species that may be excreted as such or metabolized further to ammonia water and carbon dioxide. Chitin, a polysaccharide, and its deacylated derivative, chitosan, represent the second important type of insoluble enzyme-degradable polymers. Poly- β -hydroxybutyric acid and copolymers β -hydroxybutyric and β -hydroxyvaleric acid, which are fermentation products, represent the third type, the relatively new water-insoluble enzyme-depolymerizable polymers (see Table 5). The polysaccharide and polyester types of insoluble materials are likely to undergo enzyme

Table 5 Typical examples of natural enzyme depolymerizable waterinsoluble polymers

Polymer	Class of polymer or source	Special comments
Collagen	A protein, the main constituent of connective tissues and the organic component of bones	It contains high concentrations of glycine (33%) and proline (13%); it also contains hydroxyproline (10%) and the uncommon hydroxylysine (10%)
Chitin	A natural polysaccharide obtained from crab shells	The chain is based on acetylated glucosamine units; the natural polymer can be converted to the acid-soluble partially deacetylated product chitosan
Poly- β -hydroxybutyrate and copolymers	Aliphatic polyesters of 3-hydroxybutyric acid (HB) and copolymers of HB and 3-hydroxyvaleric acid (HV)	Prepared by fermentation; most polymers are crystalline thermoplastic film and fiber-forming materials and dissolve in certain organic solvents

degradation first to water-soluble low-molecular-weight or monomeric species for their transport across biologic membranes.

SYNTHETIC BIOCHEMICALLY ABSORBABLE POLYMERS

Until the late 1960s, collagen-based surgical products (mainly sutures) dominated the field of absorbable polymers. However, a few undesirable features associated with the natural origin of these products motivated the health care community to develop synthetic, absorbable polymers with more predictable and superior properties. In the past two decades, four major synthetic, biochemically absorbable polymers were introduced in the form of surgical sutures and allied surgical devices. These are polyglycolide (PGA); 90/10 poly(l-lactide-co-glycolide) (90/10 PLG); poly-*p*-dioxanone (PDS); and copolymers of poly(trimethylene carbonate and glycolide) (18–20). Other forms of lactide–glycolide copolymers and their blends have been converted to absorbable staples (21, 22). Although several forms of polylactides, including the optically pure poly-l-lactide, have been discussed extensively by many investigators (23, 25), their marketing as useful health-care products is hardly existent. A major potential use of these polymers is likely to be in the area of bone augmentation. The degradation of the lactide-glycolide systems and PDS was examined by a few authors (18, 26–28). Although the bioabsorption of these polymers is considered to be chemically driven, a few authors advocate that lactide-glycolide polymers (29, 30) and caprolactone polymers (31) undergo enzymatic degradation.

Synthetic bioabsorbable polymers other than those made mostly from glycolide, lactide, or *p*-dioxanone have been described in the technical and patent literature (18, 32–35). Dominant among these polymers are the polyoxalates (18, 34, 35), poly(carbalkoxyalkyl 2-cyanoacrylates) (36), polyanhydrides (37, 38), and absorbable organometallic or inorganic polymers such as polyphosphazenes (39) and phosphate glass as composites in absorbable organic matrices (40). Different types of polyalkylene oxalates and isomorphous copolyoxalates (based on 1,6-hexanediol and 1,4-*trans*-cyclohexanedi-methanol) have been patented as useful bioabsorbable materials with tailored bioabsorption profiles, depending on their chemical structure, molecular weight, and morphology (34, 35). These polymers were noted as useful for the production of many surgical implants (including sutures) and surface lubricants. Polyanhydrides

such as poly(trimethylene-bis-*p*-oxybenzoic anhydride), poly(terephthalic anhydride), and their copolymers with poly(sebacic anhydride) have been synthesized, and their degradation as bioabsorbable materials was studied by Leong and co-workers (37). These polymers were indicated to be nontoxic and nonmutagenic (38). Other polymers that have been described as bioabsorbable include copolymers of poly(trimethylene malonate and *p*-dioxanone (41), polyalkylene oxamates (35), polyester-amides (42), poly-*p*-malolactone (43), copolymers of dl-lactide and ethylene oxide (44), copolymers of substituted glycolic acid and glycine (45), and poly-orthoesters (46). Modulation of the properties of biochemically absorbable polymers to impart certain desirable properties has been achieved by Shalaby and his co-workers (18, 47, 48). To increase the bioabsorption of poly-*p*-dioxane, a small proportion of codimeric sequences based on morpholinedione were introduced into the polymer main chain (49). In order to improve the radiation stability of polyglycolide and poly-*p*-dioxanone, copolymers and/or melt-blends of these polymers with a polyester based on phenylene-diglycolic acid or carboxymethylated *p*-hydroxy benzoic acid were prepared and converted to radiation-sterilizable surgical articles (47, 48, 50–53). Typical examples of the biochemically absorbable polymers and an outline of their key properties and/or applications are given in Table 6. The newly developed class of absorbable gel-former polymers is addressed below.

ABSORBABLE GEL-FORMERS AND THEIR USE AS INJECTABLE CARRIERS

Growing interest in developing absorbable pharmaceutical surgical products that degrade in the biologic environment to safe byproducts and leave no residual mass at the application site (54–60), justified the search for novel, absorbable gels. In a recent disclosure (61), a novel gel-former was described to be based on absorbable copolymers which, upon hydration, result in hydrogels that are stabilized by pseudo-crosslinks provided by a hydrophobic polyester component covalently linked to a hydrophilic component made of pharmaceutically acceptable polymer, such as polyoxyethylene. The polyester component is made of safe monomers, such as *p*-dioxanone, ϵ -caprolactone, glycolide, lactide, and mixtures thereof. Contrary to a related study (62) that describes in situ formation of biodegradable, microporous, solid implants in a living body through coagulation of a

Table 6 Typical examples of waterinsoluble chemically depolymerizable polymers

General class	Specific examples	Key properties and/or applications ^a
Poly-2-hydroxy acids and copolymers	a. Polyglycolic acid (PGA)	A, B, F, G
	b. 10/90 l-lactide/glycolide copolymer (910 polyglactin)	A, B, F
	c. Poly-l-lactide	A, B, C, D, F, G
	d. Glycolide/ε-caprolactone copolymers	A, B, G, H, I
	e. Glycolide/1,5-dioxepan-2-one copolymers	A, B, G, H, I
	f. Glycolide/trimethylene carbonate copolymers	A, B, F, G
	g. Copolymers of glycolide and polyethylene- <i>p</i> -phenylene diglycolate	A, B, G, J
Poly- <i>p</i> -dioxanone and copolymers	a. Poly- <i>p</i> -dioxanone (PDS)	A, B, F, G
	b. Copolymers of PDS and l-lactide	A, B, G
	c. Copolymers of PDS and glycolide	A, B, G
	d. Poly- <i>p</i> -dioxanone-co-morpholine-2,5 dione	A, B, G
	e. Copolymers of <i>p</i> -dioxanone and polyethylene- <i>p</i> -phenylene diglycolate	A, B, G, J
	f. Copolymers of polytrimethylene malonate and <i>p</i> -dioxanone	A, B, G, H
Polyalkylene oxalates	a. Polyesters of C4 to C16 and copolymers	A, B, C, D, E, G, H, I
	b. Isomorphous copolyoxalate of cyclic and alicyclic diols	A, B, C, D, G
Polyester-amides	Polyalkylene oxamate based on β-hydroxy-l-hexanol	A, B, G
Polyanhydrides	Copolyanhydrides of sebacic and 1,3-propane-bis-(4-oxybenzoate)	C, H

^a A = Thermoplastic crystalline polymer; B = Melt processable into fibers and films; C = Soluble in certain common organic solvents; D = Film-former by solution dipping or casting; E = Low-T_m polymer (below 100°C); F = Used to produce surgical devices; G = Patented as useful polymers for surgical and allied devices; H = Described as useful matrices for drug delivery; I = Patented as a surface coating; J = Sterilizable by gamma radiation.

solution of a polymer in an organic solvent such as *N*-methyl-2-pyrrolidone, the new hydrogel-former does not require the use of solvents. Such solvents did include low molecular organic ones that can migrate from the application site and cause damage to living tissue, such as cell dehydration and necrosis. Equally important is the fact that previously known systems are solid implants that can elicit mechanical incompatibility and, hence, patient discomfort in contrast to the new compliant, swollen, mechanically compatible hydrogels (61).

The use of absorbable gel-formers may very well lead to some of the most important applications of absorbable polymers in the pharmaceutical and biomedical industries. Among the recent activities in this area are uses of the gel-formers in 1) periodontal application of antibiotics; 2) antibiotic formulations for osteomyelitis; 3) intraocular drug delivery; 4) wound healing and hemostasis; 5) controlling the release of insulin; 6) controlling the bioavailability of ricin A-chain; 7) wound repair as a suture adjuvant; 8) modifying absorbable tissue adhesives;

9) intravaginal controlled delivery of misoprostol; and 10) sealing microporous vascular grafts. These uses are discussed next.

Periodontal Application

This entails the use of injectable gel-forming formulations for controlled delivery of antibiotics, such as tetracycline or doxycycline, for combating periodontal infections for periods of 1–4 weeks (61).

Antibiotic Formulations for Bone Infection

In a Phase I study of an NIH-SBIR program addressing osteomyelitis, available results (63) indicate that 1) selected gel-formers are capable of controlling the *in vitro* release of gentamicin and vancomycin for at least 2 weeks; 2) two types of gel-formers can be formulated, with clinically relevant doses of vancomycin, into

injectable forms; 3) injection of the vancomycin formulation about the periosteum of the goat tibia for localized drug delivery; and 4) controlled release of the vancomycin formulation is feasible without leading to toxic blood levels.

Injectable Intraocular Delivery Systems

In an SBIR (Phase I) supported by the DOD, the feasibility of using tailored gel-formers to develop an injectable, controlled release system for intraocular delivery of key drugs is being investigated. The available data indicate that:

1. Injectable gel-formers containing pilocarpine, naproxen, cyclosporin, and ganciclovir in clinically relevant doses can be prepared.
2. A continued release in a buffered medium for at least one week can be achieved.
3. Active formulations of the four drugs and a placebo can be readily injected into the vitreous cavity of the rabbit eye without eliciting unacceptable, gross tissue reactions.

Burn Wound Healing and Hemostatic Application

Preliminary results of a study supported by a DOD grant on wound healing and hemostatic agents (using hairless rats and rabbits) indicate that:

1. Certain gel-forming formulations can be used for the controlled delivery of antibiotics to incisional and burn wounds in hairless rats.
2. Incisional wound repair in hairless rats can be improved when placebo gel-formers are used.
3. Selected gel-forming formulations can induce hemostasis in a rabbit animal model.

Insulin Controlled Release Systems

Preliminary study on the use of certain gel-formers for the controlled release of insulin demonstrates the feasibility of this concept (64).

Controlled Release of Ricin A-Chain and Other Vaccines

This has been the subject of a Phase I SBIR program supported by the DOD. Results and relevant conclusions of the study (65) are summarized below. Available results

on subcutaneously (sc) administered active formulations do verify that:

1. Gel formulations can be easily prepared and appear suitable for scale-up.
2. One sc formulation is capable of releasing sufficient amounts of ricin A-chain (RAC) to elicit IgG formation at protective levels over a period of 4–6 weeks.
3. One formulation provides persistent protection for at least 6 weeks postimmunization.
4. A correlation can be established between IgG formation and the composition of the polymeric carriers.

Available Phase I results do not only fulfill these criteria but also suggest that:

1. A single-shot, absorbable sc formulation, GF-II, exhibits potentially unique in vivo performance as it comprises a microparticulate cation-exchanger.
2. Upon comparing commercial RAC solution (RAC-L) with GF-II, the latter elicits a more gradual antibody response that peaks at 10 weeks, and it exceeds a fast-decaying, initially higher response to RAC-L.
3. In terms of antibody response, GF-II is associated with higher durability over the 10 – 20 week period.
4. GF-II elicits a higher response of IgG-2A than RAC-L at 6 weeks.

Skin Wound Repair

In a study of skin wound repair, using sutures or staples on rats, it was shown that covering the wound with gel-formers allows the use of half the number of interrupted suture stitches or staples while minimizing scar formation.

Tissue Adhesive Formulation

The addition of certain members of the family of gel-formers to methoxypropyl cyanoacrylate yields a series of tissue adhesive formulations, which can be used effectively as:

1. Sutures and staples in repairing skin wounds.
2. Affixing elastin-based patches in repairing defects at certain sites of the gastrointestinal tract.

Intravaginal Controlled Delivery of Misoprostol

In a recent study, gel-formers have shown to be effective carriers for the controlled release of misoprostol in a

newly developed animal model for studying induced cervical ripening.

Sealing of Microporous Vascular Grafts

The preliminary results of a recent study on expanded Teflon® vascular grafts show that certain gel-formers can be used as sealants for these microporous implants. As sealants, they can also be used as carriers for the controlled delivery of bioactive agents to prolong patency of the grafts.

Bio-validation of Steam Sterilization

Nigel A. Halls

NHC—Nigel Halls Consulting, Chorleywood, Herts, U.K.

INTRODUCTION

The science that underpins steam sterilization is well known and has been long established. It is the preferred method of sterilization in the pharmaceutical industry; it is used for sterilization of aqueous products in a wide variety of presentations, for sterilization of equipment and porous materials required in aseptic manufacture, in microbiology laboratories for sterilizing media and other materials, and for sterilization of “massive” systems of vessels and pipework [steam-in-place (SIP) systems]. Numerous rules and guidelines have been published on the topic, yet steam sterilization and particularly bio-validation of steam sterilization is still a subject for controversy and debate.

The purpose of this article is to reexamine the bio-validation of steam sterilization, to clarify what is needed and why it is needed, and to distinguish the scientific need from the regulatory need in areas where they may appear to differ.

PRINCIPLES

Micro-organisms are inactivated when metabolically irreversible deleterious intracellular reactions occur. At high temperatures and in the presence of moisture, as in steam sterilization, the energy input from the steam inactivates micro-organisms by denaturation of intracellular proteins.

Although these reactions are complex at a biochemical level, their kinetics approximate to reactions of the first order. Thus, the kinetics of inactivation of populations of pure cultures of micro-organisms take the typical exponential form of reactions of the first order. What this means in experimental practice is that there is a linear relationship^[1] when numbers of micro-organisms held at high temperatures are plotted on a logarithmic scale against time plotted on an arithmetic scale (Fig. 1).

There are two highly significant points to be drawn from the kinetics of inactivation of micro-organisms.

First, logarithmic scales never reach zero. This means that there can never be any specifications for temperature and time which can guarantee that all micro-organisms contaminating items are going to be inactivated. However, the consequences to patients of micro-organisms surviving in allegedly sterile pharmaceutical preparations can easily be fatal. Thus, sterilization processes must be specified to ensure that the probability of micro-organisms surviving in treated items is low enough to ensure patient safety. The accepted low probability indicated in the pharmacopeias is that there should be not more than one chance in one million of viable micro-organisms surviving on a treated item. This is called a probability of nonsterility of 10^{-6} or a sterility assurance level (SAL) of 10^{-6} .

Second, the inactivation curve takes a regular form. This means that steam sterilization is a predictable process as long as some information is available (or can be safely assumed) about the numbers and thermal resistances (D_T -values, Fig. 1) of the micro-organisms contaminating items before treatment. This is important because there is no practical way to test for the achievement of SALs of 10^{-6} . The sterility or nonsterility of items cannot sensibly be confirmed in a treated item except by sacrificing the item. The pharmacopeial *test for sterility* is a sacrificial test with statistical limitations which have been so extensively criticized^[2–6] over so many decades that they should now be well understood. For instance, the sample of 20 items which is generally required in the test would allow a batch containing nonsterile items at a frequency of 1:100 to be passed on four out of every five occasions. This falls a long way short of being able to detect deviations from a standard of not more than one nonsterile item in one million.

Justification of the reliable achievement of SALs of 10^{-6} for particular pharmaceutical items treated according to particular specifications of temperature and time in particular sterilizers is predicated on the regularity and predictability of steam sterilization processes. The means of justification are through scientifically based development of sterilization specifications and sterilizer parameters,

Fig. 1 Exponential inactivation of micro-organisms (the survival curve).

and through subsequent validation of the specified processes.

DEVELOPMENT OF STERILIZATION SPECIFICATIONS AND STERILIZER PARAMETERS

The development of sterilization specifications differs from the development of sterilizer parameters. Both differ from validation (Fig. 2).

Pharmaceutical Products and Materials for Aseptic Manufacture—Sterilization Specifications

For pharmaceutical products and materials used in connection with aseptic manufacture, sterilization specifications apply to conditions of temperature and time, or F_0 , or combinations of F_0 , temperature and time to which the contaminating micro-organisms themselves must be exposed over the “hold” period of the sterilization process. In practice, this means actually within aqueous products, on the surfaces of rubber stoppers or metal machine parts, or within the folds of cartridge filters, etc.

The sterilizer parameters are the practical criteria that must be specified to ensure that the sterilization specification is delivered to all parts of the load. They always include specifications for temperature and time, but it is important to recognize the distinction between sterilizer parameters applying to the machine settings on the autoclave console, and sterilization specifications applying to actual conditions within the load. Essential sterilizer parameters also include other specifications, e.g., for load configuration, number and depth of prevacuums, cooling characteristics, etc.

Sterilization specifications are product specific. Sterilizer parameters are specific to combinations of product, presentation, and autoclave.

Sterilization specifications may be determined from theoretical considerations or from laboratory data and are within reason transferable from presentation to

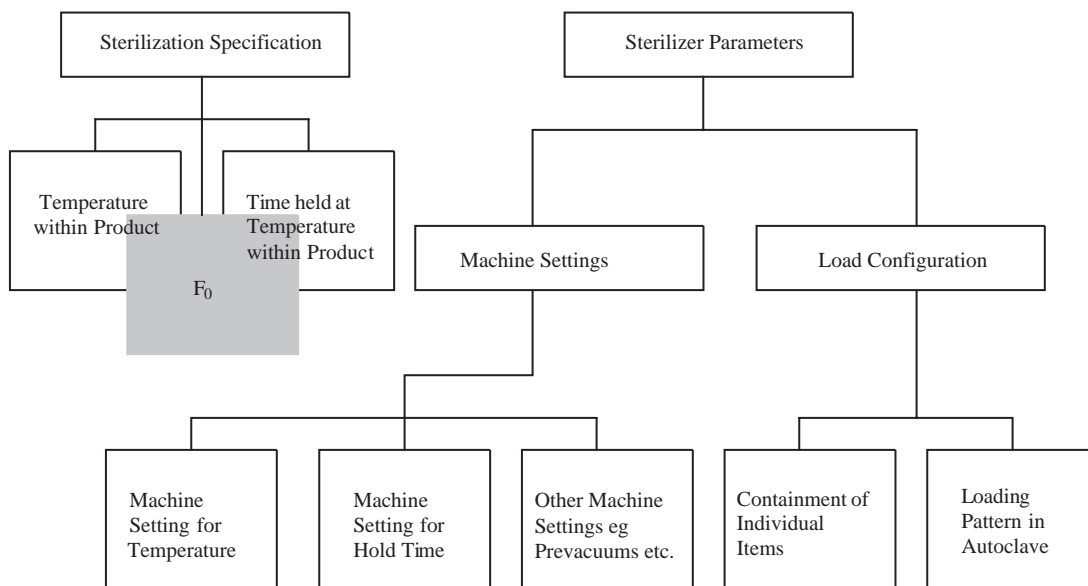

Fig. 2 Sterilization specifications and sterilizer parameters.

presentation, e.g., from 1 ml ampules to 5 ml vials to 50 ml bags. The sterilizer parameters required to deliver the sterilization specification to these presentations differ within the same autoclave and from one autoclave to another according to differences in load configurations, chamber size, steam entry points, control systems, etc. Sterilizer parameters are not transferable and must be developed empirically for each autoclave.

Sterilization specifications should be easy to develop. The pharmacopeias allow sterilization specifications to be developed from a basis of no actual data concerning the numbers and thermal resistances of micro-organisms actually contaminating the items to be sterilized. Although this statement may appear initially to be barren of scientific reason, this is in fact not the case. What the pharmacopeias provide are either a recommended overkill specification (*PhEur*) or principles for specification development (*USP*) that incorporate amounts of thermal lethality well in excess of that which could ever be practically required to obtain SALs of 10^{-6} —for this reason they are called “overkill” specifications.

In the *European Pharmacopoeia (PhEur)*, a specification of 121°C for 15 min is given as the reference condition for overkill sterilization of aqueous preparations. The *United States Pharmacopeia (USP)* defines a lethality input of 12D. These specifications merit some examination in detail.

It is worth considering the thermal resistances of micro-organisms found in pharmaceutical manufacturing environments. It is extremely rare for anyone to have isolated thermally resistant bacteria with D_{121} -values (in water) of greater than 0.3 min. The author of this paper has experience of having determined a D_{121} -value (in water) of 0.8 min for an environmental isolate of *Bacillus coagulans*, but this was several decades ago and was done with what would now be considered fairly primitive equipment. It is therefore probably quite reasonable to assume a worst case D_{121} -value of 1 min. Given this “worst case,” the *PhEur* overkill specification of 121°C would deliver 15 decimal reductions which are equivalent to assuring a 10^{-6} SAL for contaminating populations per item of up to 10^9 micro-organisms each with a D_{121} -value of 1 min. The *USP* specification of 12D under the same assumption ensures an SAL of 10^{-6} for populations of up to 10^6 micro-organisms per item.

Thus, the pharmacopeial overkill specifications provide considerable degrees of assurance that SALs of 10^{-6} will be achieved. However, these high theoretical levels of overkill are contingent upon D -values in water being reflected by D -values in or on product. Most pharmaceutical products depress the thermal resistance of micro-organisms relative to their D -values in water, but this is not universally true. Some other materials (e.g., rubber) are

known to increase the thermal resistance of micro-organisms (this may as likely be due to physical characteristics of heat transference as to biochemical protection). These product effects on thermal resistance can only be determined empirically, and are usually done in the laboratory using thermally resistant bacterial endospores, often spores of *Bacillus stearothermophilus*. Some previously unpublished guidance values on the effects of materials and pharmaceutical products on D -values of *B. stearothermophilus* relative to water are given in Table 1, and a detailed analysis has been published by Berger et al.^[7] The use of *B. stearothermophilus* for this purpose and their frequent use as biological indicators (BIs) in bio-validation have contributed to a belief that steam sterilization must be defined in terms of being able to kill this micro-organism. It is not; spores of *B. stearothermophilus* are used with steam sterilization because of the convenience of their high resistance to steam sterilization and the unique and distinctive conditions required for their recovery and growth. Indeed, some major companies use *Clostridium sporogenes* or other species of *Bacillus* as reference or indicator organisms for this purpose.

The use of “overkill” specifications is not mandatory. In some instances, there may be pharmaceutical products which are unable to withstand the temperatures or energy inputs of overkill specifications. In these cases, specifications can be developed by calculating SALs of 10^{-6} from data characterizing the number of micro-organisms actually contaminating items before sterilization treatment, or from data characterizing the actual numbers and thermal resistances of the contaminating micro-organisms. The question is this—Is this exercise worth doing or would it be better and simpler to opt for aseptic manufacture of such heat-sensitive products?

Let us consider the number of micro-organisms contaminating pharmaceutical products prior to sterilization.

Table 1 D -values of spores of *B. stearothermophilus* on various substrates relative to water (D -value approximately 4 min)

Substrate	% relative to D -value in water (100%)
Stainless steel	60
Hydrophobic filter media	90
Silicone tubing	100
Rubber stoppers (various types)	85–150
Polycarbonate	120
Two pharmaceutical products pH 3.4–3.7	15–40
Pharmaceutical product pH 10.5–10.7	115

What are the highest and the lowest numbers which could be expected? For sterile parenteral products, the highest tolerable number of micro-organisms would be expected to be on the order of 10^2 . This is because 10^3 or more per item is likely to begin to incur a risk of pyrogenicity. The lowest number which could be inferred from even an extensive number of zero counts would be one micro-organism.

Achievement of a 10^{-6} SAL from an initial bioburden of 10^2 would require eight log reductions. Applying these eight log reductions to an assumed worst case thermal resistance of D_{121} -value in water of 1 min gives a sterilization specification of 121°C for 8 min.

Achievement of a 10^{-6} SAL from an initial bioburden of 1 would require six log reductions. Applying these six log reductions to an assumed worst case thermal resistance of D_{121} -value in water of 1 min gives a sterilization specification of 121°C for 6 min.

The determination of thermal resistances is technically complex and requires special equipment (BIER Vessels). Since it is unlikely that *Bacillus* spp. can be excluded from any survey of microbiological contamination, it is reasonable to assume that spores with D_{121} -values on the order of 0.3 min will be isolated. Using this figure, SALs of 10^{-6} can be calculated at 121°C for 2.4 min for bioburdens of 10^2 , and at 121°C for 1.8 min for bioburdens of one micro-organism per item.

The range of sterilization specifications calculable by these various approaches is summarized in Table 2. It is apparent that very brief sterilization specifications (on the order of 2–3 min holding time at 121°C) are obtainable when the microbiological contamination is completely characterized in terms of numbers and thermal resistances. In practice, such limits on hold times could be difficult to control precisely, are probably insignificant in terms of thermal lethality compared with heat-up and cool-down times, and could prove difficult to “sell” to regulators. Without complete thermal characterization of thermal resistances, specifications calculable by the “bioburden”

approach are hardly significantly shorter than “overkill” specifications. Thus, it probably makes practical sense in most cases to choose only between overkill cycles for thermally resistant products and aseptic manufacture for heat-sensitive products.

Some products may be heat sensitive only above a threshold temperature; for those that can withstand temperatures in the range of 110–118°C but cannot withstand 121°C it is possible to apply the F_0 concept to the principles above and derive equivalent sterilization specifications to those given in Table 2. These specifications are summarized for 116°C in Table 3. As can be seen, if there is a requirement to sterilize at (say) 116°C, there are considerable time savings to be obtained by characterization of the contaminating micro-organisms.

Pharmaceutical Products and Materials for Aseptic Manufacture—Sterilizer Parameters

Sterilizer parameters are specific to combinations of product, presentation, and autoclave. They must be established empirically. Heat penetration studies done prior to the performance qualification phase of validation serve the purpose of determining the loading patterns, prevacuums, and temperature and pressure settings, etc. which ensure that the sterilization specification is delivered to the product and that it is delivered uniformly throughout the load.

For instance, a particular proposed loading pattern may never allow for uniform conditions (within specified limits) to be achieved throughout the load. In this case the pattern would have to be changed. Or, in a particular autoclave it may be necessary to set the temperature at 122°C for 121°C to be achieved within the load.

Air removal is particularly important in porous and equipment loads, but is usually of little importance in the sterilization of aqueous pharmaceutical products. Air removal can be important to the specification of new

Table 2 The range of sterilization specifications at 121°C calculable according to various approaches

autoclaves—those which are to be designated only for aqueous product sterilization have no need for the pumps and ancillary equipment required to pull deep vacuums.

The involvement of steam in the sterilization of different types of product is an important consideration in understanding and controlling autoclaves.

For aqueous products, steam is solely a means of raising the product to the specified sterilizing temperature; the steam does not come into contact with the contaminating micro-organisms. The transfer of heat energy (lethality) to the contaminating micro-organisms is from the product itself. To all intents and purposes any suitable form of energy source could be used to raise the temperature of the product. For instance, if ampules of aqueous products were to be sterilized in a hot air oven, the mechanisms of microbial inactivation would still be by coagulation of intracellular proteins. However, heat transfer from hot air is much slower than heat transfer from steam, which is why this is not seen as a practical process. Microwave irradiation could be an alternative means of sterilizing aqueous pharmaceutical products utilizing the same anti-microbial mechanisms as steam; certainly there is evidence that microwave killing patterns are mainly due to heat transfer with very little direct energy being absorbed from the microwaves.^[8,9]

For porous and equipment loads, the steam comes into direct contact with the contaminating micro-organisms on the materials being sterilized and there is no intermediary in the transfer of heat. The energy content of steam is defined by its latent heat. If the steam is pure in the sense that it contains neither entrained gas nor moisture, an amount of energy defined by its latent heat at the pressure of the steam will be transferred to the micro-organisms by condensation on their surfaces.

There are many potential pitfalls in equipment and porous load sterilization, mainly concerned with air or other noncondensable gas. First, the purity of the steam is important; if it is carrying moisture, or noncondensable gas,

it will not contain the same amount of energy as pure steam and its lethality will be less than that predicted for pure steam. Second, any residual air around the contaminating micro-organisms may insulate them from contact with the steam and thus reduce the amount of energy (lethality) transferred. In this type of sterilization, steam quality becomes very important and so also do the materials and manner in which the products are contained in steam-permeable wrapping or perforated trays, etc., within the autoclave, and the number and depth of evacuations of the autoclave prior to the temperature-hold phases. Thermal monitoring alone gives little information on the adequacy of the measures put in place to control these complex factors, and it is therefore generally thought essential that some empirical studies be done with BIs as part of process development to ensure that the thermal lethality being imparted by the steam is not being impeded. These development studies may be rolled into bio-validation.

Sterilization of Microbiological Media in the Laboratory

The various suppliers of microbiological media include recommendations for sterilization in their catalog under “Directions for Use,” for instance, “sterilize by autoclaving at 121°C for 15–18 min.” The question that must be asked is—What do these specifications mean?

Are they intended to apply within the media as are the sterilization specifications for pharmaceutical products and materials for aseptic manufacture? Or are they sterilizer parameters? There may be some indication in some of the older suppliers’ manuals which expand their recommendations along the lines of “sterilize by autoclaving at 15 psi (121°C) for 15–18 min.” Since pressures of 15 psi are not achievable within media, it is clear that the intention was that the recommendations be applied to sterilizer parameters.

In most cases, it is probably immaterial how these recommendations are interpreted. For media, “overcooking” is bad because of deleterious effects on growth-support characteristics, and “undercooking” is generally self-disclosing through evident contamination.

SIP Systems

Systems that are sterilized in-place are often immensely complex. The initial challenges to their sterilization are the removal of air and the elevation of the temperature of the pipework to prevent heat losses and condensation. As such, most work in the development of sterilization specifications for SIP systems is concerned with the heat-up phase. Appropriate questions are: Is the sterilization temperature achieved throughout the system? Where is the slowest location to achieve temperature? Where should the control probe be located?

Often vast amounts of thermal lethality calculated as F_0 -values are delivered in these prehold stages of SIP. However, because these temperatures are being achieved in the presence of steam–air mixtures, it is not correct to assume that the biological lethality during the heat-up phase of SIP systems is equivalent to that achieved with pure steam.

The time for which the system must be held at temperature (the sterilization specification) is often relegated to a minor consideration compared with this earlier development work. Typically, it is decided arbitrarily to use, 121°C for 15, 20, or 30 min, with no real scientific basis.

Perhaps, a basis parallel to that of the pharmacopeial overkill specifications could be developed. For instance, if the actual maximum number of micro-organisms within an SIP system is assumed to be 10^{12} (since this would amount to a few grams of biomass it certainly should be maximal), then 18 log reductions would be required to ensure not more than one chance in a million of a survivor. An overkill cycle of 121°C for 20 min could be proposed by adding two log reductions as a safety factor and assuming each micro-organism to have a D_{121} -value of 1 min.

BIO-VALIDATION

The performance qualification (PQ) phase of validation follows the development of the sterilization specifications and of the sterilizer parameters which will deliver them. The purpose of PQ in steam sterilization of pharmaceutical products, equipment, laboratory media, and SIP systems is to confirm that the sterilization specification consistently achieves its intended purpose. The process is run using the parameters derived from process development on (usually)

three separate occasions and tested for compliance with a variety of predetermined acceptance criteria. As a subset of PQ, the purpose of bio-validation is to confirm that the lethality expected from the process does not significantly deviate from what is expected. Bio-validation is a “test” of consistency. If the acceptance criteria are not achieved, there may be need for more process development.

In consideration of the extent, thoroughness, and history of the research evidence that micro-organisms are inactivated in a regular fashion in response to temperature and time, it is periodically suggested that bio-validation should not be necessary where there is evidence of adequate heat penetration. In practice, however, the expected lethality may not always be achieved. Most frequently, such deviations from ideality occur in equipment and porous load sterilization because of inadequate air removal. Where deviations from ideality occur for aqueous pharmaceutical products, they most likely arise from inadequate knowledge of how the product affects the thermal resistances of micro-organisms, but this is best determined in the laboratory at an earlier stage of process development, not at the bio-validation “milestone” later in the critical path of product introduction.

Acceptance criteria for bio-validation of steam sterilization processes are usually (but not invariably) defined along the following lines:

- n BIs will be placed in the load at locations defined in a drawing.
- Each BI will contain at least 10^6 viable spores of *B. stearothermophilus*.
- The load will be exposed to a defined autoclave treatment (the validation cycle).
- Bio-validation will be considered satisfactory if no viable spores are recovered from the BIs after x days of incubation at 55–60°C.

Because this approach is the common practice, there is a widely held belief within the pharmaceutical QA community that the ability to inactivate 10^6 spores of *B. stearothermophilus* is a synonym for achieving an SAL of 10^{-6} . It is not. It is true, however, that inactivation of 10^6 spores of *B. stearothermophilus* with the pharmacopeially approved minimum D -value of 1.5 min in 10–100 replicates guarantees achievement of better than 10^{-6} SALs for worst case bioburdens (Table 4). However, Table 4 also shows that the converse, i.e., failing to inactivate 10^6 spores of *B. stearothermophilus*, does not necessarily mean that a 10^{-6} SAL has not been achieved.

Another area of confusion is that the USP definition of an overkill specification—“a lethality input of $12D$ ”—can be demonstrated directly in bio-validation. It should be

Table 4 Sterility assurance levels indicated by inactivation of 10^6 spores of *B. stearothermophilus*

	Spore <i>D</i> value			
	1.5 min	2 min	3 min	4 min
Bioburden of 10^2 micro-organisms per item each with <i>D</i> -values of 1 min	10^{-10}	10^{-14}	10^{-22}	10^{-30}
Bioburden of 10^2 micro-organisms per item each with <i>D</i> -values of 0.3 min	10^{-38}	10^{-51}	10^{-78}	10^{-104}
Bioburden of 1 micro-organism per item each with <i>D</i> -values of 1 min	10^{-12}	10^{-16}	10^{-24}	10^{-32}
Bioburden of 1 micro-organism per item each with <i>D</i> -values of 0.3 min	10^{-40}	10^{-53}	10^{-80}	10^{-106}

Inactivation of 10^6 spores in 10–100 replicates is assumed to be equivalent to 8 log inactivations.

understood that the maximum number of log inactivations of any bacterial population is technically limited to about 9 or 10 *D*-values. The maximum number of micro-organisms that can be handled as a BI is about 10^7 – 10^8 , the sensitivity of recovery of micro-organisms is restricted to more than 10^{-2} . An indirect demonstration of 12 log inactivations of a micro-organism with a *D*-value of 1 min can be achieved by showing inactivation of 10–100 replicate BIs each carrying 10^6 spores with *D*-values of 1.5 min, or by inactivation of 10–100 replicate BIs each carrying 10^4 spores with *D*-values of 2 min. Direct demonstration of 12*D* is technically impossible.

In bio-validation, the spore of *B. stearothermophilus* is akin to an end-point analytical reagent. For instance, when litmus changes from blue to red at pH levels below 7, it shows only that the pH is not higher than 7. By killing all of 10–100 replicate BIs with 10^6 spores having *D*-value 1.5 min, all that is proven is that the thermal lethality delivered is not less than an F_0 of 12 min. The *PhEur* overkill sterilization specification of 121°C for 15 min should meet this requirement easily, and so should any other longer specification at 121°C, or any specification for longer times at lower temperatures taking into account of the F_0 concept.

Numbers and Locations of BIs for Bio-validation

It is usual for bio-validation to be done with an arbitrary number of BIs between 10 and 100. Both limits are based on practical considerations.

The lower number of BIs is defined in terms of ensuring that bio-validation addresses sufficient parts of the load for confidence that items in all parts of the autoclave are receiving the required lethality. Normal practice is to

define this number in terms of placing at least as many BIs as the number of thermal probes used for thermal qualification. It is sensible to place one BI alongside each thermal probe in order to be able to relate thermal data to biological data. In addition to this, some BIs should be placed in other nonprobed locations in consideration of the possibility that the leads to the thermal probes may be acting as conduits for air removal or steam penetration, and thus provide falsely high levels of lethality.

More often than not the number of BIs used is about 20–30. Larger numbers up to 100 may be necessary to address very large autoclaves or in thermal mapping studies, but in validation there is little extra statistical confidence to be gained by doing so. In most microbiology QA laboratories, 20–30 BIs can be handled conveniently.

Periodically in the bio-validation of sterilization of porous or equipment “minimum” loads, it is not practical to locate 20 or 30 BIs. For instance, a minimum load may be one cartridge filter, one mop head, or one machine manifold. In such cases, it is important to avoid too much distortion of the statistics of bio-validation. At least five BIs are recommended no matter how difficult it may be to place them.

Choice of BIs

Spores of *B. stearothermophilus* are most commonly used for bio-validation of steam sterilization processes. This is not to say that it is mandatory to use *B. stearothermophilus* nor that it is used exclusively. Other micro-organisms, e.g., *sporogenes*, are used by some companies and accepted by the regulatory agencies. Use of *B. subtilis* spores with resistances to steam sterilization in the higher range of that found in natural bioburden has, in recent years, been criticized by European regulatory agencies.

The principles underlying the choice of micro-organism used as BIs are quite well known:

- The micro-organisms must have high resistance to the sterilization treatment which they are being used to validate. This does not mean that they must be the most resistant micro-organism known to man. *B. stearothermophilus* has D_{121} -values of 1–4 min according to conditions of culture and the substrate upon which they are mounted. This is higher than most spores of *Bacillus* spp., which tend to have D_{121} -values below 0.5 min.
- The micro-organisms must have stable resistances to the sterilization treatment which they are being used to validate. There are data from commercial suppliers of BIs to show that spores of *B. stearothermophilus* survive and retain stable resistances over long periods of crudely controlled storage.
- The micro-organisms must be easily culturable and preferably be easily identifiable in culture. Very few micro-organisms share with *B. stearothermophilus* the ability to grow in simple culture media at 55–60°C.

It is customary to use 10^6 (in practical terms 10^5 – 10^7) spores per BI. This number is based on custom, practice, and convenience rather than on science. Larger numbers than this are difficult to handle in culture and result in large errors in counting. Smaller numbers reduce the sensitivity of the test. Unfortunately, the widespread use of 10^6 spores for bio-validation has (as described before) led to a confusion between 10^{-6} SALs and 6 log reductions of *B. stearothermophilus*.

More complex decisions surround the choice of substrate within which spores are suspended or on which they are mounted for use as BIs.

The decision tree shown in Fig. 3 may be used to help choose the spore substrate used in bio-validation of aqueous pharmaceutical products. To use this decision tree, it is essential to have some knowledge of the effects of product on the resistance of spores; as mentioned before, this requires special equipment and experience.

In all circumstances water is the preferred substrate for bio-validation of aqueous pharmaceutical products. Where water would give deceptive results, it should not be used.

- If the D_{121} -value of *B. stearothermophilus* is higher in the product than it would be in water (i.e., the product makes the spores more resistant to steam sterilization), then bio-validation must be done with the spores suspended in product. Otherwise falsely favorable results may occur.
- If the D_{121} -value in product of *B. stearothermophilus* is equal to or less than its D_{121} -value in water, and the

sterilization specification is based on overkill, then bio-validation must be done with spores suspended in water. However, if the sterilization specification has been “tailored” specifically to the resistance of micro-organisms in the product, then bio-validation must be done with the spores suspended in product. Otherwise falsely unfavorable results may occur.

Under no circumstances must spores be suspended in product if that product is sporicidal.

For other materials (for instance, equipment and supplies for aseptic manufacture) where the mechanisms of inactivation rely on direct contact between the steam and the item being sterilized and therefore where air removal is matter of importance, the choice of substrate for BIs generally lies between using commercially available paper spore strips and the material itself. The decision tree in Fig. 4 may be helpful. Regulatory pressure is currently toward use of inoculated product, but commercially available spore strips are more convenient. “Tailor-made” inoculated product requires substantial amounts of microbiological expertise. The decision tree in Fig. 4 may be helpful in selecting which approach is best in particular circumstances.

Use of commercially available BIs transfers much of the responsibility for assuring quality in manufacture to the supplier. Regardless of this, their quality must be controlled on receipt and prior to use in bio-validation. There is no reason why any microbiology laboratory should not verify the numbers of spores per commercial BI. On the other hand, the determination of resistance requires special equipment and expertise and is probably best accepted on the basis of the supplier’s certification. If this is done, the user of the BIs is responsible for knowing what the certified measures of resistance mean, how they were determined (on the strips, in aqueous suspension, or in or on something else), and that they were determined correctly and in compliance with applicable standards and legislation.

Validation Cycle

Bio-validation is usually done against a sterilization specification which delivers less lethality than the lower limit of lethality allowed by the sterilization specification defined for the material being sterilized. It is clearly intellectually flawed to choose to validate something different to that which is ever to be used in practice. So what is the reasoning behind this practice?

Sterilization specifications in the “hold” period are presented in terms of temperature and time with upper and

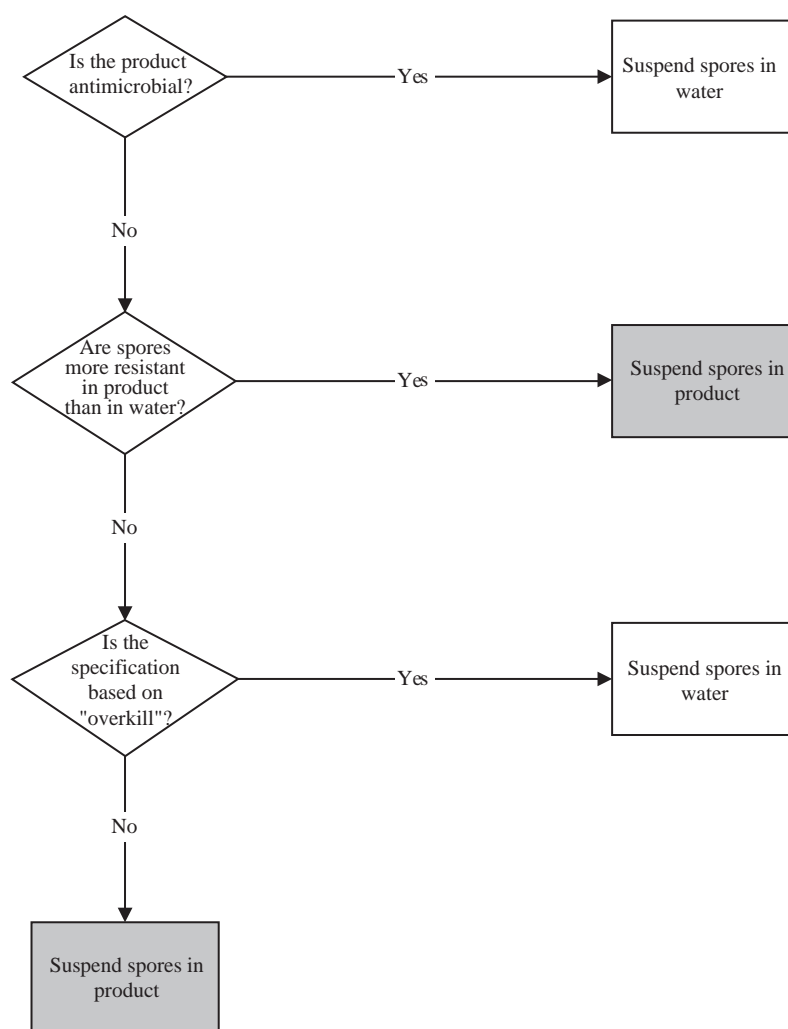

Fig. 3 Recommended substrates for BIs used in bio-validation of aqueous fluid loads.

lower tolerances set around them. The lower specification limits are critical to sterilization.

Time is generally easily controllable to quite high levels of accuracy and precision: A steam valve allows steam to enter the autoclave until the hold temperature is reached; the valve is then closed and the process is controlled by a timer which, at the end of the specified hold period, sends a control signal to activate the exhaust valves and cooling sequences. The hold time is usually specified in terms of whole minutes—well within the accuracy and precision of all but the most inappropriate of timers.

Temperature is less easy to control precisely. The temperature in the hold period in autoclaves is generally maintained by modulating valves which open to allow steam entry when the temperature (or pressure, because these valves are more often than not controlled through pressure transducers) begins to drop toward the critical lower limit

of the specification. It is generally not possible to control an autoclave to run through a complete hold period at the lower limit of its temperature specification. However, even quite apparently trivial errors in temperature above or below the limit can make significant differences in the amount of lethality delivered. For instance, at a nominal temperature of 121°C, an error of 1 K can increase or decrease the amount of lethality by 25%.

Bio-validation cycles are therefore designed to ensure that no more lethality is delivered than that specified by the lower limits of lethality of the sterilization specification used in routine practice. Ideally this is done by reducing the time of the hold period, but sometimes, when quite short cycles are being used, it may also be necessary to reduce the temperature set point on the autoclave as well. The risk in all of this is that the bio-validation cycle is used as a justification for the release of sterilized items when

Fig. 4 Recommended substrates for BIs used in bio-validation of porous loads.

specifications are not complied with under atypical production conditions. This idea should not be entertained.

Acceptance Criteria

Bio-validation is a limit test, which at best produces quantal data. Each BI should be tested separately for survivors or absence of survivors. The acceptance criterion should be that there are no survivors.

Detection of survivors in all exposed BIs is clearly unacceptable; such a result would be obtainable if the BIs had never been near a sterilizer.

Data showing survival on some but not all of the BIs may be valuable in process development (particularly in the development of sterilization specifications and sterilizer parameters for porous and equipment loads), but would likely raise issues at regulatory inspection. The inference taken from having some survival could be that each item in the autoclave load is not being exposed to the same treatment.

For initial validation of a newly developed process, complete inactivation of all BIs should not be difficult to achieve.

The range of D_{121} -values acceptable to USP for spores of *B. stearothermophilus* allowed as BIs for use in steam sterilization is 1.5–3.0 min. An overkill sterilization or bio-validation specification delivering an F_0 of 15 min would deliver 10 log inactivations or, if there were 10^6 spores per BI, one chance in one million of finding a survivor on any one BI, one chance in one thousand of finding a survivor in 10 BIs, one chance in one hundred of finding a survivor in 100 BIs, and so on. In other words,

there are pretty long odds against failing the acceptance criteria.

However, spores of *B. stearothermophilus* may have D_{121} -values of 3 min. In such a case there would be practically no chance of meeting the acceptance criteria of killing 10^6 spores with an F_0 of 15 min. What are the implications of this?

On the face of it, the implication is that this sterilization specification/sterilizer parameters combination is invalid. However, remember that this same sterilization specification/sterilizer parameter combination would have been valid if the BIs used had D_{121} -values of 1.5 min. In practical terms the pharmacopeial specification for thermal resistance in BIs has been set naively. Many companies purchasing spores of *B. stearothermophilus*, either for preparing BIs or as commercial strips, order against their own specifications which include upper D_{121} -value limits (in water) of around 2 or 2.5 min. The author of this paper has published recommendations^[10] for determining bio-validation cycles appropriate to challenge numbers and D_{121} -values of the spores available, but in the long run it is far more convenient and easier to justify compliance to regulatory agencies when there is bio-validation to show that 10^6 spores have been inactivated in 10–100 replicates.

Requalification

Periodically it is wise to repeat bio-validation. Changes do occur in autoclaves and no change control procedure, no matter how rigorously implemented, is infallible. The

purpose of requalification is to determine if any unforeseen change has arisen to affect the sterility assurance provided to the items being sterilized.

It is important for requalification that the numbers, resistances, and substrates for the BIs are closely similar to those used in the initial validation. For the same reasons as resistance variation within BIs as discussed before, it is possible if these factors are not well controlled to emerge from requalification with either a false confidence in the security of the process (use of BIs which are less resistant than those used in initial validation), or with the incorrect opinion that the process has failed (use of BIs which are more resistant than those used in initial validation).

Biological requalification is usually done following significant process changes or on an annual frequency. The establishment of a frequency should, in principle, be based on business risk; in fact, however, with well-designed and controlled autoclaves, the risk to the business of extending the interval beyond 1 yr is probably more one of incurring regulatory criticism at inspection than of releasing nonsterile products to market.

Bio-validation of Laboratory Autoclaves Used for Sterilizing Microbiological Media

It is not difficult to argue that the effectiveness of sterilizing microbiological media is self-disclosing and should not therefore merit bio-validation. The pertinence of bio-validation to the qualification of laboratory autoclaves is more to do with having confidence in the sterility of media before or after it is used in the laboratory (and risk false positive results if the media is not sterile), or take it into (say) aseptic manufacturing areas for environmental monitoring (and if it is nonsterile contaminate areas and products which may otherwise have been secure). Many regulatory bodies see bio-validation of laboratory autoclaves as mandatory.

Bio-validation of Steam-in-Place (SIP) Systems

SIP systems range from very small systems (say, a mixing tank) where all parts may reach temperature within 2 or 3 min, to absolutely massive arrangements of vessels, valves, and pipework in which the expulsion of air, the drainage of condensate, and the attainment of the

sterilization specification temperature at the “slowest point” can take 20 or 30 min.

Bio-validation is essential. The placement of BIs is largely a matter of judgment. Certainly the “slowest point” to reach the sterilization specification temperature must be challenged. Certainly vent filters and low points where condensate could accumulate must be challenged. Thereafter, it is a regulatory expectation that there should be sufficient BIs placed to give coverage to the whole system, which in effect may mean placing BIs in locations which, due to the heat-up time of the system, have been exposed to the sterilization specification temperature for two, three, or four times longer than the “slowest point.” Undue confidence should not be taken from favorable results from these locations.

AUTOXIDATION AND ANTIOXIDANTS

John M. Pezzuto

Eun Jung Park

University of Illinois at Chicago, Chicago, Illinois, U.S.A.

INTRODUCTION

By definition, oxygen is an absolute requirement for aerobic life, but it may also be viewed as toxic under certain conditions. A chemical reaction that usually takes place at ambient temperature between atmospheric oxygen and an organic compound is generally defined as autoxidation. The phenomena of autoxidation are commonly observed in everyday life. For example, the browning of fruit, deterioration of edible oils, and degeneration of old rubber bands are the results of autoxidation. In the human body, reactive oxygen species (ROS) produced during autoxidation processes are also commonly encountered. This is a normal part of human physiology, as long as defense systems are effective, but overproduction or failure to scavenge free radicals can result in toxic biological responses that can yield deterioration and degeneration of cells, tissues, or organisms.

There are numerous reports suggesting that free radicals are involved in various human disease states (Table 1). Pathological phenomena related to autoxidation are due to reactive oxygen species, and most age-related diseases can be explained through reactions of free radicals with biological substances. A notable case is cancer or, more specifically, carcinogenesis. Free radicals play a critical role in the initiation of carcinogenesis by damaging nucleic acids and producing a variety of lesions. For example, 8-hydroxyguanine, 5-hydroxymethyluracil, and thymine glycol are formed by the attack of hydroxyl free radicals on deoxyribonucleic acid (DNA), and these mutations may be viewed as a cause of carcinogenesis. Another free radical-related disease state is stroke. Damage to the brain due to central nervous system (CNS) ischemia is caused by injury resulting from the interruption of blood flow (i.e., lack of oxygenation) which is then followed by reoxygenation of the brain (ischemia/reperfusion). It appears that all or most aerobic tissue suffers damage once it undergoes an ischemia/reperfusion insult. The severity depends on many factors, one of which is the length of the ischemic period. Considerable evidence is now accumulating that injury occurs almost exclusively during the reperfusion

phase, and that the injury is due to oxygen free radical-mediated oxidative stress. Furthermore, some neuronal pathologies, such as Alzheimer's disease, may relate to lipid peroxidation of cell membranes by free radicals.

Autoxidation phenomena could be completely prevented by total exclusion of oxygen or other oxidizing substances from a biological system. This is generally not practical, but changes in endogenous factors, such as addition of inhibitors, may decrease the reaction rate or prolong the induction period. However complete prevention of autoxidation is unlikely. Substances that can suppress autoxidation are termed inhibitors or antioxidants. Preventive inhibitors decrease the rate of autoxidation by suppressing the rate of initiation reactions. Antioxidants in the true sense are substances that can inhibit propagation steps; that is, they interrupt autoxidation chain reactions. Other types of inhibitors, for instance, antiozonants, are not biologically relevant but may be important in industry (e.g., protective coatings). Antioxidants are known to inhibit carcinogenesis or atherosclerosis. For example, vitamins and phenolic compounds can function as chemopreventive agents. The mechanism of action and the biological role of autoxidation and antioxidants are discussed in this article.

AUTOXIDATION

Autoxidation Reactions

The majority of compounds that are subject to autoxidation are unsaturated substances or highly condensed polymers, and the target of ROS is commonly the diene functionality—or double bonds. Autoxidation of unsaturated lipids is a good model to demonstrate this mechanism. The initial reaction between molecular oxygen and a polyunsaturated fatty acid (PUFA) occurs as $\text{RH} + \text{O}_2 \rightarrow \text{ROOH}$, which involves the movement of a double bond as well as the insertion of oxygen. In general, there is a “spin barrier” that prevents the direct addition of ground-state molecular oxygen in a single step to an organic compound. In the case of autoxidation, since direct addition is eliminated by the

Table 1 Structural and functional alterations of biological entities produced by radicals or ROS

Structure alterations	Functional alterations	Disease
Lipid peroxidation	Increased permeability of membrane	Cancer
Protein adducts	Impaired response of membrane to signals	Stroke
Hemoglobin adducts	Altered enzyme activity	Alzheimer's disease
	Reduced affinity of binding proteins	Rheumatoid arthritis
	Altered uptake of oxidized entities	Cataract

spin barrier, the alternatives are i) electron transfer (i.e., redox reactions) involving, for example, a transition metal ion, or ii) the participation of free radicals, whereby the addition of a radical to molecular oxygen can give rise to another radical (1).

The important features of autoxidation are autocatalytic and free radical chain reactions. The rate of oxidation is initially slow and increases as the reaction progresses. However, once autoxidation is initiated, the reaction continues until the reaction substrate or catalytic factor becomes extinct. In short, unsaturated lipids undergo three reaction phases: initiation, propagation, and termination. The participation of reactive oxygen radicals in autoxidation reactions is summarized in the following reaction steps.

Initiation is perhaps the process most difficult to define. This is because of the very low concentration of radicals and the likelihood of there being more than one process, since a large number of different radicals can abstract hydrogen from RH to form $R \cdot$. For example, $X \cdot$ may be a transition-metal ion, a radical generated by photolysis or high-energy irradiation, a radical obtained by decomposition of a hydroperoxide (e.g., $RO \cdot$), or a radical formed from an exogenous initiator. The two propagation reactions form the basis of the chain-reaction process. The autoxidation reaction is generally assumed to be a very fast reaction with almost no activation energy. A major consequence of this phase is that the concentration of $R \cdot$ is much smaller than that of $RO_2 \cdot$. Like initiation processes, termination reactions may also be divided into

those involving organic free radicals exclusively, and those in which metal ions participate. Of the termination processes involving $R \cdot$ or $RO_2 \cdot$, the biomolecular reaction

has received the most attention since this is likely to be the most important termination reaction under physiological conditions.

Autoxidation of unsaturated lipids is affected by many factors, so that none can be considered exclusively prooxidative or antioxidative. The rate of autoxidation is increased with reactivity of the autoxidizing substrate, concentration of reactants (the number of active sites and the concentration of oxygen), modified physical factors (e.g., a rise in temperature or by irradiation), and especially with an increase in the rate of initiation reactions (1). The rate of chain initiation reactions is increased mainly by factors that increase free radical function in autoxidizing systems, for example, ultraviolet, X-Ray, or ionizing radiation. In various reactant systems, such as fats, oils, and biological membranes, heavy metals and their derivatives are important initiators of autoxidation reactions. The reaction rate, however, is suppressed by factors such as a reduction in the number of active sites, a decrease in the partial pressure of oxygen by a suitable selection of physical factors, and a decrease in the reaction temperature. The most important, however, is the reduction of initiation rate (i.e., the level of free radicals capable of chain initiation). Substances actively suppressing the concentration of the free radicals are antioxidants. Other substances are also very effective in suppressing autoxidation, particularly those eliminating free radical precursors (e.g., sulfur compounds that cause reduction of lipid hydroperoxide) (2). Substances deactivating ozone (antiozonants) or singlet oxygen, which protect against irradiation, or heavy metals (metal scavengers), also act as inhibitors of lipid autoxidation.

Lipid Peroxidation

Oxidative damage to membrane lipids (i.e., lipid peroxidation in biological systems) has been studied for many years. Lipid peroxidation is a primary event produced by oxidative stress or as a consequence of tissue damage, which can exacerbate tissue injury, due to the potential cytotoxicity and genotoxicity of the end products of lipid peroxidation. Membrane lipids with double bonds are most susceptible to oxidation. Lipid peroxidation can reduce membrane fluidity, leading to increased rigidity throughout the hydrophobic space of membranes, decreased permeability, osmotic fragility, and altered activity of certain membrane-bound enzymes and transport systems (3).

Membrane lipid peroxidation can change the activity of essential membrane proteins such as Na^+/K^+ -ATPase. As a consequence, rates of ion pumping may be altered (4). Two well-characterized products of lipid peroxidation, malondialdehyde and 4-hydroxynonenal, have been shown to react with critical biomolecules that may have a key role in the development of certain pathological states. Microsomal lipid peroxidation forms mainly 4-hydroxy-2-nonenal with minor amounts of 4-hydroxy-2-octenal, 4-hydroxy-2-decenal, and 4-hydroxy-2-undecenal. α,β -Unsaturated aldehydes, such as 4-hydroxynonenal, are highly reactive electrophilic reagents that react easily with thiols by Michael addition to the $\text{CH}=\text{CH}$ double bond (1,5). Aldehyde adducts of lipid peroxidation have been shown to induce glutathione depletion in hepatocytes, and corresponding abnormal liver function (6, 7). Free hemoglobin, in the presence of xanthine/xanthine oxidase, will also promote the peroxidation of arachidonic acid and unsaturated fatty acids within normal cellular membranes. Furthermore, hemoglobin or red cell lysates cause brisk peroxidation of crude murine brain homogenates. This hemoglobin-driven peroxidation is blocked by an iron chelator (i.e., desferrioxamine) which indicates that iron released from heme is responsible (8).

Peroxides can play a physiological role in the cell but also mediate processes leading to heart disease and carcinogenesis (9–11). Fatty acid peroxidation may also be related to free radical-mediated metabolic activation of carcinogens or drugs, which lead to the initiation of carcinogenesis or cytotoxicity. Modification of membrane function as a consequence of lipid peroxidation includes uncoupling of oxidative phosphorylation in mitochondria, alteration of liver endoplasmic reticulum functions, and modification of the ionic permeability of phospholipid membranes. Radiation-catalyzed lipid peroxidation of erythrocyte membranes increases

permeability to Na^+ , K^+ , and Ca^{++} . Ultimately, peroxidation leads to gross destruction of membranes, as demonstrated by release of lysosomal enzymes in irradiated lysosomes, hemolysis in irradiated erythrocytes, and release of various enzymes by disruption of the liver plasma membrane.

FREE RADICALS AND DEFENSE SYSTEMS

Free Radicals and Defense Systems

A free radical may be broadly defined as a molecule or ion containing an unpaired electron (Table 2). Although most radicals are reactive and undergo dimerization or other reactions in which the unpaired electron becomes paired some radicals such as nitroxide radicals ($\text{R}_2\text{NO}\cdot$) are relatively stable. A major source of radicals in biological systems is molecular oxygen. This very reactive molecule is essential to the life of higher organisms, but nevertheless can be considered dangerous in excess.

Superoxide anion ($\text{O}_2^{\cdot-}$) and hydrogen peroxide (H_2O_2) are normal metabolites in mammalian cells produced during the biological reduction of oxygen. The occurrence of oxidative radical reactions in biological systems is usually associated with cellular electron transfer chains of the mitochondria and certain enzyme activities. Free radicals are further generated during the course of specialized physiological reactions, such as the release of $\text{O}_2^{\cdot-}$ and H_2O_2 by endothelium noninflammatory cells, which might serve as cell signals promoting growth responses. Furthermore, environmental factors as well as the metabolism of xenobiotics are significant sources of free radicals, although their actual contribution to the redox state of the cell is difficult to assess.

Although of modest chemical reactivity, $\text{O}_2^{\cdot-}$ and H_2O_2 contribute to the formation of more reactive species via various redox reactions. It is currently accepted that the reaction of both $\text{O}_2^{\cdot-}$ and H_2O_2 with suitable metal complexes yields $\text{HO}\cdot$. Fenton-type reactions requires both $\text{O}_2^{\cdot-}$ and H_2O_2 as precursors of $\text{HO}\cdot$. This proceeds via an intermediate catalyst, such as a transition metal chelate, which reacts to produce $\text{HO}\cdot$ (12). $\text{HO}\cdot$ may account for some aspects of mitochondrial damage, such as oxidative impairment of mitochondrial DNA. The requisite conditions for $\text{HO}\cdot$ formation by mitochondria are met during mitochondrial electron transfer: mitochondria are a major source of $\text{HO}\cdot$ generated by H_2O_2 cleavage.

Haber – Weiss reactions: $\text{Fe}^{3+} + \text{O}_2^{\cdot-} \rightarrow \text{Fe}^{2+} + \text{H}_2\text{O}_2$

Fenton reaction: $\text{Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{3+} + \text{HO}\cdot + \text{HO}^-$

Table 2 Principal reactive oxygen intermediates formed by cells

ROS	Function
Superoxide anion, $O_2^{\cdot-}$	One-electron reduction products of O_2 , produced by phagocytes; formed in autoxidation reactions; generated by oxidases (heme protein).
Hydrogen peroxide, H_2O_2	Two-electron reduction product of O_2 ; formed from $O_2^{\cdot-}$ by dismutation or directly from O_2 . Reactivity of $O_2^{\cdot-}$ and H_2O_2 amplified in the presence of heme protein.
Hydroxyl radical, $HO\cdot$	Three-electron reduction product of O_2 generated by Fenton reaction; transition metal (iron, copper)-catalyzed Haber–Weiss reaction; formed by decomposition of peroxynitrite produced by the reaction of $O_2^{\cdot-}$ with $NO\cdot$.
Nitric oxide, $NO\cdot$	Generated from arginine via NO synthase in an O_2 -dependent reaction; in the absence of O_2 , formed by Fe^{2+} -mediated nonenzymatic generation from tissue NO_2^- .

(Adapted in part from Ref. 15.)

Another type of one-electron transfer reaction that contributes to the formation of oxyradicals involves the quenching of carbon center radicals ($R\cdot$) by molecular oxygen. This reaction leads to the formation of peroxy radicals ($R-OO\cdot$), which generally have quite different reactivities from those of the parent $R\cdot$ species. As a result of the reactivity of these species toward unsaturated fatty acids, the propagation steps of lipid peroxidation follow the initiation step. These propagation steps occur at membrane hydrophobic sites, and the length of the chain reaction is determined by the availability of reactants, PUFA and O_2 , and of chain-breaking antioxidants such as α -tocopherol, carotenoids, and ubiquinone.

In cells, the first line of defense against these reactive species is represented by primary antioxidant defenses involving enzymes that specifically remove free radicals or oxidants, such as superoxide dismutase, glutathione peroxidase, and catalase. In general, aerobes do not express an excess of antioxidant defenses, although these systems are often inducible by elevated O_2 if sufficient time for adaptation is allowed. Moreover, endogenous antioxidants may not prevent damage by ROS at ambient O_2 . Thus, animals rely on a second line of defense in the form of repair systems, the most important of which removes mutagenic lesions in DNA induced by ROS. Superimposed on such defenses are inducible proteins such as heme oxygenase-1. Heme oxygenases remove the prooxidant heme and produce the antioxidant bilirubin in the process (13). Additional protection is provided by dietary antioxidants. The physiological role of some of these is well established (e.g., vitamin E and ascorbate), whereas the role of others (e.g., flavonoids, carotenoids) is currently uncertain. However, dietary antioxidants appear to be important in delaying/preventing certain human diseases, especially cardiovascular disease and some types of cancer (14).

Antioxidants

Natural antioxidants such as nonenzymatic dietary components are not specific but can scavenge organic and inorganic radicals. These agents are found in numerous plant materials and commonly include an aromatic ring as part of their molecular structure. There are a variety of cyclic ring structures that are generally associated with one or more hydroxyl groups to provide a labile hydrogen and a basis for free radical formation. These antioxidants can be classified as water soluble or lipid-soluble, depending on whether they act primarily in the aqueous phase or in the lipophilic region of cell membranes. Hydrophilic antioxidants include ascorbic acid and urate. Ubiquinols, retinoids, carotenoids, flavonoids, and tocopherol are representative lipid-soluble antioxidants (Fig. 1). Plasma proteins, glutathione, and urate are endogenous, whereas ascorbic acid, carotenoids, retinoids, flavonoids, and tocopherols constitute some of the dietary antioxidants. These compounds possess the potential to scavenge and quench various radicals and ROS. Certain radical scavengers are not recyclable, however, others are recycled through the intervention of a series of enzyme systems or other nonenzymic antioxidant systems.

Based on safety and other pragmatic reasons, the number of active substances used as antioxidants is restricted to a few phenolic substances. The flavonoids are an unusually large group of naturally occurring phenolic compounds ubiquitously distributed in the plant kingdom (Fig. 2). These aromatic compounds are formed in plants from the aromatic amino acids, phenylalanine, tyrosine, and acetate units. Phenylalanine and tyrosine are converted to cinnamic acid and *p*-coumaric acid that condense with acetate units to form the cinnamoyl structure of the flavonoid (15). Flavonoids are generally

Fig. 1 Natural antioxidants.

known to be plant, flower, leaf, and fruit pigments. They are responsible for the brilliant shades of blue, scarlet, orange, etc., in flowers, fruits, and leaves. They are found in various fruits, vegetables, nuts, seeds, grains, spices, and herbs, as well as in beverages such as tea, cocoa, and wine. Dietary exposure to flavonoids is significant. The average diet in the United Kingdom and United States may contain up to 1 g of mixed flavonoids per day. Their dietary intake far exceeds that of vitamin E (a monophenolic antioxidant) and β -carotene (15).

Flavonoids act as potent metal chelators and free radical scavengers. They are powerful chain-breaking antioxidants (16). Moreover, flavonoids are known to possess vitamin C stabilizing and antioxidant-dependent vitamin C sparing activities. They are also known to increase the absorption of vitamin C. In addition, flavonoids are known to modify the activities of a host of enzyme systems including protein kinase C, protein tyrosine kinase and various other kinases, aldose reductase, myeloperoxidase, NADPH oxidase, xanthine oxidase, phospholipase, reverse transcriptases, ornithine decarboxylase, lipoxxygenase, cyclooxygenase, and so on. Some of these enzyme systems are critically involved in immune function, carcinogenesis, cellular transformation, and tumor growth and metastasis. The physiologic and pathologic processes affected by flavonoids are diverse and numerous, and include secretion, mitogenesis, platelet aggregation and adhesion to endothelial surface, cell motility and malignant cell proliferation, cancer metastasis, and function/expression of adhesion molecules in various mammalian cell types. The antioxidant function

and enzyme-modifying actions of flavonoids could account for many of their pharmacological activities (15).

Quercetin and other flavonoids are effective inhibitors of $O_2^{\cdot -}$ -production by cells. Quercetin is a potent inhibitor of human neutrophil degranulation and $O_2^{\cdot -}$ -production, and also inhibits the phosphorylation of neutrophil proteins accompanying neutrophil activation by phorbol myristate acetate (17). Quercetin can also suppress lipid peroxidation in several biological systems, such as mitochondria, microsomes, chloroplasts, and erythrocytes. Silymarin, a 3-OH flavone present in *Silybum marianum* (the European milk thistle), protects rat liver mitochondria and microsomes from lipid peroxide formation induced by Fe^{2+} -ascorbate and NADPH- Fe^{3+} -ADP systems (18). Soybean isoflavonoids have shown antioxidative potency and prevent peroxidative hemolysis of sheep, rat, and rabbit erythrocytes (15). Quercetin and silybin (19) were reported to exert a protective effect by the decrease in the xanthine dehydrogenase/oxygenase ratio observed during ischemia/reperfusion in the rat. The enzyme (xanthine oxidase) implicated in tissue oxidative injury after ischemia/reperfusion is a source of ROS that is formed from a dehydrogenase during ischemia. The protective effect of quercetin and silybin on the xanthine dehydrogenase/oxidase ratio is due to inhibition of the dehydrogenase.

PROOXIDANTS

A prooxidant is an agent that can induce oxidative stress, which is defined as a shift in the prooxidant-antioxidant balance toward oxidant activity. Oxidative stress induced by a prooxidant in a biological system manifests itself as increased production of bioactive free radical species, a decrease or modulation of antioxidant defenses, and/or an increase in oxidative damage. The fine balance between the oxygen center radicals and antioxidants may be dependent on the concentration of prooxidant, oxygen tension, and interactions with other antioxidants.

Vitamins

Carotenoids

Carotenoids are a well-characterized class of pigments widely distributed in nature and responsible for the bright colors of various fruits and vegetables. Some of the more than 600 different carotenoids are well known, such as β -carotene, which is widely used as a precursor of vitamin A, a food colorant, and a food additive (22). These

Fig. 2 Phenolic antioxidants isolated from plants; **1.** quercetin; **2.** silymarin; **3.** *trans*-resveratrol; **4.** piceatanmol; **5.** chlorogenic acid methyl ester (16, 17); **6.** 1-(3',4'-Dihydroxycinnamoyl)-cyclopenta-2,5-Diol (16); **7.** 1-(3',4'-Dihydroxycinnamoyl)-cyclopenta-2,3-Diol (16); **8.** kaempferol-3-*O*-neohesperidoside (17); **9.** 5,6,7,4'-Tetrahydroxyflavonol-3-*O*-rutinoside (22); **10.** floribundones I; **11.** floribundones II, **12.** (-)-epicatechin-3-*O*-gallate; **13.** curcumine.

compounds have been shown to function as enhancers of gap–junction communication, stimulants of immune responses, and quenchers of electronically excited species, such as singlet oxygen and triplet sensitizers (23–25). The action of β -carotene and other carotenoids as antioxidants has recently attracted widespread attention. Carotenoids are thought to scavenge free radicals, and the antioxidant action of β -carotene and other carotenoids has been observed with in vitro and in vivo systems (26, 27). However, carotenoids do not have structural features commonly associated with chain-breaking antioxidants. The extensive system of conjugated double bonds in their molecules imparts a prooxidant character and makes them very susceptible to attack by free radical species (Fig. 3).

The development of either a harmful or beneficial cellular response by carotenoids will depend on their antioxidant or prooxidant characteristics, which are determined by various factors in the intra- and extracellular environments such as oxygen tension and β -carotene concentration. When an inappropriate prooxidant activity of carotenoids develops in normal cells, the reactive oxygen metabolites generated could induce damage to lipids, proteins, and DNA. This effect alters normal regulatory functions and can damage cellular integrity or induce neoplastic transformation. Some human intervention trials indicate that carotenoid supplements are of little or no value in preventing chronic disease, such as cardiovascular disease and cancer, and may actually increase lung cancer incidence in smokers (22). In contrast, when carotenoids act as prooxidants in already transformed cells, they could induce beneficial effects, such as inhibiting the growth and development of malignant lesions and/or producing tumor cytotoxic effects (28).

Although it has been reported that carotenoids may prevent normal cells from becoming transformed through their antioxidant activity, there is much evidence indicating that they may also block the growth of cells already

transformed through their prooxidant action. Carotenoid autoxidation has been suggested to occur at a higher level in tumor cells than in normal cells. In tumor cells, therefore, it can be hypothesized that the prooxidant properties of carotenoids prevail over the antioxidant properties (29). In addition, some studies have shown that carotenoids act as prooxidant agents selectively in tumor cells by increasing the expression of heat-shock proteins (30) and enhancing the formation of lipid peroxidation products, further reducing the levels of oxygen-protective enzymes and stimulating the expression of tumor necrosis α -factor.

Ascorbates

Ascorbate is an essential vitamin that must be taken from external sources. It is marketed as a dietary supplement because of its antioxidant properties. Several epidemiologic studies suggest that antioxidant vitamins in sufficient concentrations inhibit heart disease and cancer. However, there is considerable uncertainty about the optimal level of intake. Substantial evidence shows that ascorbate can also act as an oxidant, depending on the environment in which the molecule is present. It can induce cell death, nuclear fragmentation, and internucleosomal DNA cleavage in human myelogenous leukemic cell lines (29). More recently, it was reported that dietary supplementation of 500 mg/day of vitamin C to healthy volunteers for 6 weeks results in significant prooxidant effects. This is exemplified by an increase in lymphocytes with typical markers of DNA damage, mediated by oxygen radicals such as 8-oxoguanine and 8-oxoadenine (31).

Vitamin C supplementation is able to significantly affect CYP2E1-catalyzed drug metabolism in the rat and is linked to an overgeneration of the superoxide anion in hepatic microsomes. Generation of a superoxide anion induced by vitamin C supplementation provides a plausible explanation for the observed damage to DNA in peripheral blood lymphocytes (32). Ascorbate is a reducing agent in brain tissue homogenate but has an oxidizing effect in brain slices. A hypothesis put forth to explain the oxidative effects of ascorbate in cortical slices proposes that extracellular ascorbate is oxidized to dehydroascorbate which is rapidly carried into cells via a glucose transporter. The dehydroascorbate in cytosol is then reduced back to ascorbate, and, during the reduction process, cellular components are oxidized (Fig. 4) (33).

Tocopherols

Vitamin E, the major lipophilic antioxidant of exogenous origin in tissues, is the collective name for the eight major naturally occurring molecules, four tocopherols and four tocotrienols, that qualitatively exhibit the biological

Fig. 3 Proposed reaction pathway of β -Carotene prooxidant activity. β -C, β -carotene; $\text{ROO}\cdot$, peroxy radical; $\text{ROO-}\beta\text{-C}\cdot$, β -carotene radical; $\text{ROO-}\beta\text{-C-OO}\cdot$, β -carotene peroxy radical; $\beta\text{-CO}$, β -carotene epoxide; $\text{RO}\cdot$, alkoxy radical. Fig. 4 Structure of the reduced and oxidized forms of vitamin C.

activity of α -tocopherol. α -Tocopherol is generally regarded as the most important lipid-soluble antioxidant in plasma, circulating lipoproteins (34), and tissues, whereas γ -tocopherol and tocotrienols are present in these tissues at much lower concentrations (Fig. 5).

In an investigation of the antitumor activities of α -tocopherol acid succinate and acetate, the acid succinate form inhibited the growth of oral carcinoma cells, while stimulating the growth and differentiation of normal keratinocytes (35). The acetate form increased thymidine incorporation and mutant p53 expression in cancer cells, thereby increasing proliferation and expression of the cyclin regulator p34cdc. Vitamin E treatment reduced the time required for wound healing in the oral cavity and increased the in vitro growth of endothelial cells (36). Platelet adhesion was also inhibited, resulting in a possible reduction in thrombosis. The mechanism of action for this response appears to be blockage of the prostaglandin pathway at the site of cyclooxygenase activity, and it is a plausible mechanism that supports the use of vitamin E in periodontal disease (29).

The antioxidative activity of vitamin E is converted to prooxidant activity when mild conditions were used to initiate oxidation. A prooxidant effect of α -tocopherol on lipid peroxidation was found only when the samples were virtually free of ascorbate, or if the final concentration of ascorbate in the samples was physiologically low. Adding ascorbate to a near-physiological final concentration restored the antioxidant activity of α -tocopherol under mild oxidative conditions (37).

Retinoids

Retinoids, metabolic and synthetic derivatives of vitamin A, have been shown to function as effective antioxidants and inhibit the peroxidation of PUFA in lipid bilayers. For example, several retinoids inhibit ascorbate-dependent, iron-catalyzed lipid peroxidation in rat liver microsomes and brain mitochondria. Retinol palmitate was shown to function as an antioxidant in rat heart and brain tissues (38). However, retinoic acid was shown to stimulate the rate of 2,2'-Azobis(2-Amidinopropane)-initiated autoxidation of linoleic acid in sodium dodecyl sulfate micelles, and this observation may account for the prooxidant effect of retinoic acid in this system (39). In addition, possible

detrimental effects of retinoids (e.g. promotion of tumor growth), increase in low-density lipoproteins (LDL) and triglyceride, and exacerbation of preexisting autoimmune disease have all been reported (40).

Phenolics

Phenolics are one of the major groups of nonessential dietary components that have been associated with the inhibition of atherosclerosis and cancer. The bioactivity of phenolics may be related to their antioxidant behavior, which is attributed to their ability to chelate metals, inhibit lipoxygenase, and scavenge free radicals. However, phenolics can also function as prooxidants by chelating metals in a manner that maintains or increases their catalytic activity (Fig. 6). Also, polyphenolics reduce metals, thereby increasing their ability to form free radicals from peroxide.

Flavonoids

Flavonoids, especially, those with catechol or pyrogallol groups, obviously are prone to autoxidation reactions (40). In a recent paper by Morgan et al. (41), the prooxidative and antioxidative properties of phenolics from soybeans and other legumes were documented. The primary phenolics (phenolic acids) and flavonoids were able to reduce ferric to ferrous ions and were able to chelate and alter the catalytic activity of iron. Most of the phenolics tested were also able to inhibit oxidation of linoleic acid micelles and ferrous ion-catalyzed oxidation of glutamine synthase, presumably through free radical scavenging and removal of iron from catalytic sites via chelation. Although flavonoids inhibited oxidation in certain systems, they did not protect against all forms of oxidative damage. The phenolics chelated iron, but this metal ion was still catalytically active and able to oxidize both deoxyribose and DNA. Prooxidant activity of phenolics has also been observed for carnosol, carnosic acid, quercetin, rutin, and luteolin (41).

It was also found that pH was essential in determining the oxidative role of phenolics. In general, a decrease in pH increased iron-reducing activity and reduced the ability of phenolics to chelate and inhibit the catalytic activity of iron. Increasing pH increased deoxyribose and DNA oxidation. Inhibition of lipid oxidation was also influenced by pH, with γ -resorcylic acid being antioxidative at pH 5.8 and prooxidative at pH 7.4. Hydrobenzoic acid was antioxidative, and apigenin-7-glucoside was prooxidative at pH 7.4, yet neither had an effect on lipid oxidation at pH 5.8. These results suggest that the pH of biological tissues could also influence the antioxidative/prooxidative activity of phenolics (42).

Fig. 5 Chemical structures of the vitamin E groups and metabolic pathway of α -Tocopherol.

A possible mechanism of cytotoxicity in polyphenols may be related to their prooxidant properties (43). Flavonoids autoxidize in an aqueous medium and may form highly reactive HO^\bullet radicals in the presence of

transition metals. In addition, polyphenols and flavonoids may act as substrates for peroxidase and other metalloenzymes, yielding quinone- or quinomethide-type prooxidant and/or alkylating products. The prooxidant character

Fig. 6 Antioxidant and prooxidant functions of ubiquinone.

of polyphenol cytotoxicity is supported by the formation of activated oxygen species during gallic acid induced apoptosis, and by the enhancement of gallic and caffeic acid induced apoptosis by non toxic concentrations of copper ions (44).

Catechins, such as (–)-epicatechin and (–)-epigallocatechin abundant in green tea, possess the antioxidative and prooxidative characteristics of Cu^{2+} -induced LDL oxidation. In the initiation phase, LDL oxidation was inhibited by addition of catechin. In contrast, during the propagation phase of LDL oxidation, catechins served as accelerators of oxidation. Depending on redox status, they might form reactive oxidation products such as semi-quinones and quinones and function to stimulate oxidative reactions (44).

Quercetin, a highly studied antioxidant flavonoid has the potential to inhibit free radical processes in cells by a) scavenging $\text{O}_2^{\cdot-}$, b) blocking lipid peroxidation, c) reacting with peroxy or lipid peroxy radicals, d) inhibiting formation of HO^{\cdot} , and e) chelating iron

ions. The biological effects of quercetin are believed to result from its antioxidant properties. Recently, it was clearly demonstrated that quercetin could function both as an antioxidant and a prooxidant, depending on concentration and free radical sources and their location in the cell. Also, quercetin was observed to be cytotoxic in a dose-dependent manner. Although the exact mechanism of cytotoxicity has not yet been fully elucidated, it may involve formation of $\text{O}_2^{\cdot-}$ or its metabolite *o*-quinone (Fig. 7). Such species are known to be toxic and to bind irreversibly to various cell constituents by covalent binding with sulfhydryl groups or other essential groups (45).

Catecholestrogens

The antioxidant properties of estrogens have been demonstrated in many in vitro and in vivo studies (46–48). For instance, estrogens inhibit the oxidation of LDL, the peroxidation of lipids, and the oxidation of cholesterol. The administration of 17β -estradiol to ovariectomized pigs inhibits the oxidation of LDL. This

Fig. 7 A simple scheme of quercetin oxidoreductive activation.

effect has also been observed in postmenopausal women after administration of 17 β -estradiol. These antioxidant activities of estrogens are believed to explain the lower rate of heart disease in premenopausal women, or postmenopausal women treated with estrogen, compared to that of men (49).

In contrast, prooxidant effects of estrogens have been established in other model systems (50). 17 β -estradiol or other estrogens induce single-strand breaks or 8-hydroxylation of guanine bases of DNA in Syrian hamsters treated with these hormones. Moreover, metabolites of estrogen or diethylstilbestrol in the presence of peroxidase and DNA induce 8-hydroxylation of guanine bases. In addition to oxidant-induced damage of DNA, estrogens have also been shown to generate lipid peroxidation and oxygen-radical-mediated oxidation of amino acid residues of proteins, resulting in carbonyl-containing moieties (50).

Estrogens may exhibit either pro- or antioxidant activities depending on the nature of their metabolites and concentrations (Fig. 8). Pharmacological concentrations of parent hormones or their metabolites clearly have antioxidant properties. This inhibitory mechanism may be based on the free radical scavenging action of the phenol moiety of estrogen. In contrast, 2- or

4-hydroxyestradiol enhances the oxidation of LDL by decreasing lag times of lipid peroxidation by 40–50% compared to control values in the absence of estrogen. The catechol structure of catecholestrogens appears to be necessary for this prooxidant activity, as the parent hormones and other estrogen metabolites do not possess any detectable oxidant activity. Therefore, the *in vivo* prooxidant activity of estrogens may be dependent on their conversion to catecholestrogen metabolites in a specific organ or species. The mechanism of prooxidant activity of catecholestrogens is likely based on the reduction of metal ions, specifically Cu²⁺ to Cu⁺, by the catecholestrogen metabolites. The lipid oxidation of LDL by Cu⁺ generated hydroxyl radicals, which further initiate oxidation of lipids (51).

DISEASES ASSOCIATED WITH FREE RADICALS

Ischemia/Reperfusion Injury

The syndrome of ischemia/reperfusion (I/R) injury has been characterized in recent years for the heart, brain, intestine, kidney, and other organs. This phenomenon

Fig. 8 The metabolites of estrogen.

consists of a paradoxical increase in tissue injury during the reperfusion period in an organ that has sustained relatively minor damage during a period of ischemia. It is now evident that reperfusion tissue injury is mediated through oxidant mechanisms associated with the generation of oxygen-based radicals. ROS have been implicated in both the myocardial dysfunctions that are observed during reperfusion following short periods of ischemia (the stunned myocardium) and the irreversible injury to cardiac myocytes that occurs during reperfusion after longer periods of ischemia (52).

Infusions of high concentrations of the catecholamines, epinephrine, or norepinephrine into experimental animals are known to produce myocellular mitochondrial swelling, myofibrillar disruption, plasma membrane blebbing, and myocardial necrosis. It has been suggested that these cardiotoxic effects result not from the catecholamines themselves but from the production of $O_2^{\cdot-}$ and H_2O_2 formed by a complicated series of reactions during the autoxidation of catecholamines. It was observed that vitamin E deficient rats were more sensitive to the cardiotoxic effects of isoproterenol, whereas myocardial damage induced by this synthetic catecholamine was reduced when the diet was supplemented with vitamin E. However, the results of studies demonstrating protection by antioxidants against catecholamine-induced myocardial necrosis must be interpreted with caution since accumulation of neutrophils, a major source of oxygen radicals, has been observed in such model (53).

Carvedilol, a potent antioxidant, prevents the lipoperoxidation of mitochondrial membranes, which suggests a strong contribution to the known cardioprotective activity of this compound through protection of mitochondrial function (54).

A similar cardioprotective benefit is achieved by agents and antioxidant enzymes that scavenge hydroxyl radicals (or reduce their formation), but not by agents that reduce superoxide anion production. Some compounds of plant origin that have been shown to protect against ischemic injury are procyanidine from *Vitis vinifera* (55), resveratrol from red wine (56), and ginseng extract (57).

Cancer-Carcinogenesis

The progression of tumor formation may be slow, often taking 10 years or more. It is important that carcinogenesis can be viewed as a multistage, microevolutionary process. It is generally agreed that cancer can be derived from a single abnormal cell, and work with experimental systems shows that carcinogenesis is divisible into three major stages: initiation, promotion, and progression. Initiation is

a heritable aberration of a cell. Such initiated cells can undergo transformation to malignancy if promotion and progression follow. Initiation appears to be irreversible and can result from DNA damage. Promotion, however, is affected by factors that do not alter DNA sequences; it involves the selection and clonal expansion of initiated cells. This process is partly reversible and accounts for a major portion of the lengthy latent period of carcinogenesis. The final stage of tumor formation is the progression of a benign growth to a malignant neoplasm. There is loss of growth control, an escape from the host defense mechanism, and metastasis.

Certain initiators, such as radiation or chemical carcinogens, can induce the production of various free radicals and subsequent DNA base sequence alteration. In addition, cells of the immune system (e.g., neutrophils and macrophages) produce $O_2^{\cdot-}$ and H_2O_2 , which have been associated with the induction of experimental cancers. Oxygen free radicals and methyl radicals are known to damage DNA. In some cases, such free radicals may arise in reactions catalyzed by ferric and cupric ions localized in the vicinity of cellular DNA. Free radical mediated DNA damage can have serious consequences on an organism unless the damage is repaired. Although oxygen free radical effects can lead to DNA damage, they may also directly affect the protein components of the DNA repair apparatus. Unrepaired DNA alterations are inherited as mutations.

Oxygen radicals and related species may also be involved in tumor-promotion. Tumor-promoting phorbol esters not only can induce changes in cellular genes leading to some of the phenotypic characteristics of tumor cells, but they also can stimulate inflammatory leukocytes to release superoxide. The release of superoxide by phagocytic cells following stimulation with phorbol esters is proportional to their tumor-promoting activity. Low levels of both $O_2^{\cdot-}$ and H_2O_2 , products of the "respiratory burst," can promote fibroblast growth, possibly fibroblasts that harbor an oncogene or a mutated protooncogene. Also, low levels of superoxide can stimulate growth or growth responses in a variety of cell types when added exogenously to culture medium. In particular, these species stimulate the activation and translocation of protein kinase C, as well as the expression of early growth-regulated genes such as the protooncogenes *c-fos* and *c-myc*. Superoxide and/or hydrogen peroxides might function as mitogenic stimuli through biochemical processes common to natural growth factors. Thus, signaling of growth responses involving released superoxide or hydrogen peroxide may be mediated through the oxidative modification of components of the signal transduction pathway. It is also possible that oxidative

inactivation of serum protein inhibitors allows proteases to remodel the cell surface, thereby facilitating (modulating) the action of normal growth factors (58).

A final and decisive step in carcinogenesis is the invasion and metastatic spread of the tumor to various body spaces and cavities. This appears to be facilitated by the activation of genes for the release of proteolytic enzymes. Although high levels of immune cells appear to favor cell killing, lower numbers of immune cells can favor metastasis. Again, the released superoxide may serve to promote metastatic growth. Alternatively, superoxide could inactivate serum antiproteases, some of which are extremely sensitive to oxidative inactivation (59).

In addition, lipid peroxidation is associated with some phases of carcinogenesis. There is increasing evidence that covalent binding of carcinogens or toxic substances to cellular macromolecules, particularly those carrying genetic information, is the primary event in the initiation of carcinogenesis. Thus, covalent binding to macromolecules could be the basis of many pathological changes induced by toxic substances. The ultimate forms of xenobiotics are believed to be reactive electrophilic metabolites, which combine with nucleophilic groups of macromolecules. It is also possible that miscoding or mutagenesis may be of minor importance in the initial events of chemical carcinogenesis, and that genetic transpositions, including relatively large regions of the genome, may be more relevant (60).

The DNA adducts, deoxyadenosine and deoxyguanosine, which are induced by malondialdehyde, the end-product of lipid peroxidation, accumulate in human breast tissues. These adducts are present at relatively higher concentrations in breast cancer cells compared to normal breast cells (61). In a recent study, serum antioxidative vitamin levels and lipid peroxidation were compared in gastric cancer patients (62). The level of serum ascorbic acid, α -tocopherol, β -carotene, and retinol were assessed. The levels of ascorbic acid in patients with gastric carcinoma were less than one-fifth of that in the control group, and the production of β -carotene and α -tocopherol were decreased, as well.

Neuronal Disease

Lipid peroxidation of biological membranes gives rise to degeneration of synapses and neurons, and may be observed in stroke, or neuronal disorders such as Alzheimer's, Parkinson's and Huntington's diseases. Oxidative stress and damage are accepted features of neural degeneration. The pathological presentation of Alzheimer's disease, the leading cause of senile dementia,

involves regionalized neuronal death and accumulation of intraneuronal and extracellular lesions (63). 4-Hydroxynonenal mediates oxidation-induced impairment of glutamate transport and mitochondrial function in synapses (64). Amyloid β -protein may be involved in modulation of membrane lipid peroxidation. Amyloid β -protein fragments 25–35 [A-beta (25–35)] inhibit lipid peroxidation at low concentrations as a result of physicochemical interactions with the membrane lipid layer (65). Further, there is close association between increased levels of the antioxidant enzymes superoxide dismutase and heme oxygenase-1 and cytoskeleton abnormalities found in Alzheimer's disease (66).

DETECTION AND CHARACTERIZATION OF FREE RADICALS

ROS have been involved in the pathogenesis of a variety of human diseases. Their injury potential and pathologic role demand quantitative methods that are diagnostic of the process and that meet basic analytical criteria regarding accuracy, reliability, sensitivity and specificity. In addition, the determination and quantification of antioxidant activity is necessary for the discovery and evaluation of drug candidates (67). However, because of their reactive nature and short half-lives, it is difficult to quantify ROS. Alternatively, analyses involving secondary or end products produced by the attack of ROS on lipids, enzymes, or other cellular components are generally preferred. In spite of recent advances in technology, however, these indirect methods often give misleading results due to their poor specificity and sensitivity.

Chemiluminescence Measurements

Chemiluminescence is the production of light generated from chemical sources. The quantum yield of photons for intrinsic (nonstimulated) or native reactions are low but organic substances are able to undergo an oxidative reaction that can be sufficiently exothermic to produce an emitting state. Generally, the light produced is in the visible range (400–600 nm), but UV or infrared emission is possible.

Due to potential variability and low intensity of native chemiluminescence, enhancer compounds have been introduced (68). These compounds were selected primarily as a result of their high quantum efficiency and photon yield after oxidation. Luminol and lucigenin are enhancers for oxygenation when added to an *in vitro* biological

system and form high levels of excited-state products and chemiluminescence. These compounds react with all species of oxidants to form 3-aminophthalate and *N*-methylacridone, respectively. The excited electrons in these compounds revert to their ground state with the emission of energy as light, which can be detected by photomultipliers. The sensitivities of luminol and lucigenin vary. Luminol detects H_2O_2 , $\text{HO}\cdot$, hypochloride, peroxy nitrile and lipid peroxy radicals, whereas lucigenin is particularly sensitive to the superoxide radicals. Chemiluminescence may be utilized as a direct noninvasive method for measuring ROS, and for detection of lipid hydroperoxide, phospholipid and cholesterol hydroperoxide if cytochrome *c*-heme is added prior to luminol.

Thiobarbituric Acid (TBA) Assays

The TBA test is perhaps the most widely used method for determining lipid peroxidation. The representative adduct of lipid peroxidation, malondialdehyde, forms a 1:2 adduct with TBA that can be measured by spectroscopy or fluorometry. The general procedure, of which there are numerous variations, simply involves heating a small quantity of the test substance for a defined period of time in an aqueous acidic solution of TBA, and then measuring the absorbance (535 nm) of the red color which is produced in the TBA reaction. It should be considered as an index of oxidative stress that represents primarily lipid peroxidation (69).

Chemical Measurement of Superoxide Radical

The reduction of yellow nitroblue tetrazolium (NBT) to blue formazan is applied as a probe of $\text{O}_2^{\cdot -}$ generation in biological systems. This reaction is utilized in demonstrating the role of phagocytes (neutrophils and monocytes/macrophages) in the host response to infection and inflammation. Oxygen is rapidly reduced via a complex NADPH-oxidase system composed of a flavoprotein and a cytochrome. The cytochrome has a sufficiently low midpoint potential to allow the direct catalytic transfer of electrons from NADPH to oxygen resulting in the production of superoxide.

The respiratory burst of phagocytic cells can be assessed by incubating a suspension of cells in an isotonic solution of the yellow oxidized nitroblue tetrazolium dye. During this process, the soluble dye interacts with the cytoplasmic components associating with the oxidant species generated. NBT reduction by activation cells in the presence of superoxide dismutase has been shown to be markedly reduced (70), which suggests the major oxidant

species responsible for the reduction of dye to a black-blue deposit called formazan is superoxide. The overall degree of NBT reduction in a given cell population can be quantified by measuring the concentration of reduced NBT or formazan spectrophotometrically.

Cytochrome *c* Reduction Assay Using a HL-60 Cell Culture System

HL-60 is an acute human premyelocytic leukemia cell line derived by Collins et al. (71), of which about 10% spontaneously differentiate. Various differentiation inducers, such as DMSO, TPA (12-*O*-tetradecanoylphorbol 13-acetate), or retinoic acid, lead to the differentiation of HL-60 cells through the monocyte or granulocyte pathways. HL-60 cells treated with DMSO appear as granulocytes with morphological and functional changes including production of superoxide anion and phagocytosis. Respiratory burst due to phagocytosis produce ROS such superoxide anion in the nonmitochondria oxidase system. In a simple assay procedure, HL-60 cells differentiated by treatment with 1.3% DMSO are stimulated to produce superoxide anion by addition of TPA, and cytochrome *c* oxidized by superoxide anion is measured by absorbance at 550 nm (72).

Xanthine/Xanthine Oxidase Assay

Xanthine oxidase is an obvious candidate for the production of oxygen free radicals. This enzyme is localized in the liver, small intestinal mucosa, and vascular endothelial cells, and catalyzes the hydroxylation of many purine substrates. It converts hypoxanthine to xanthine and then to uric acid in the presence of molecular oxygen to yield superoxide anion. During ischemia, xanthine dehydrogenase is converted to the oxidase form. At the same time, ATP is degraded to hypoxanthine that accumulates in ischemic tissue. On reperfusion, with the readmission of large quantities of molecular oxygen in the presence of high concentrations of hypoxanthine that is the other substrate for xanthine oxidase, there may be a burst of superoxide anion production. With in vitro systems, antioxidant activity can be measured by the absorbance of uric acid (292 nm) which is produced by xanthine oxidase. If a test sample inhibits the enzyme, xanthine oxidase cannot produce uric acid from xanthine (73).

DPPH Assay

DPPH (1,1-diphenyl-2-picrylhydrazyl) is a purple-colored stable free radical that is reduced to the yellow-colored

diphenylpicrylhydrazine by free radicals. The DPPH assay measures one electron, such as hydrogen atom donating activity and hence provides a measure of free radical scavenging activity. This assay is suitable for the initial screening of multiple samples, such as plant extracts. Reaction mixtures containing test samples dissolved in DMSO and DPPH in absolute ethanol are incubated at 37°C for 30 min in a 96-well plate and absorbance measured at 515 nm (74).

CONCLUSIONS

As summarized in this article, ROS are involved in reactions of importance in human disease states. A mechanistic understanding of these pathological processes is beginning to emerge. As a result, intervention strategies can be devised and antioxidants are receiving a great attention as potential drugs. While it is clear that prevention of oxidative damage should have a beneficial effect on human health in general, the possibility of prooxidant activity leading to adverse health effects must be strongly borne in mind. A number of assay systems are currently available for thorough characterization of the large number of potential antioxidants which are known, or for the discovery of new chemical entities. With these tools and prudent preclinical and clinical studies, it should be possible to devise dietary strategies or pharmaceutical preparations that will reduce morbidity and mortality.

ACKNOWLEDGMENT

The authors extend great thanks to Dr. Ghee T. Tan for review of this manuscript. Laboratory work conducted in this area is supported by program project P01 CA48112 awarded by the National Cancer Institute.

INTRODUCTION

Biopharmaceutics is the study of the interrelationship of the physicochemical properties of the drug [active pharmaceutical ingredient, (API)] and the drug product (dosage form in which the drug is fabricated) based on the biological performance of the drug (Table 1).

Biopharmaceutics also considers the impact of the various manufacturing methods and technologies on the intended performance of the drug product. Biopharmaceutics uses quantitative methods and theoretical models (1) to evaluate the effect of the drug substance, dosage form, and routes of drug administration on the therapeutic requirements of the drug and drug product in a physiological environment.

Bioavailability is often used as a measure of the biological performance of the drug and is defined as a measure of the rate and extent (amount) to which the active ingredient or active moiety becomes available at the site of action. Bioavailability is also a measure of the rate and extent of therapeutically active drug that is systemically absorbed.

Biopharmaceutics allows for rational design of drug products to deliver the drug at a specific rate to the body in order to optimize the therapeutic effect and minimize any adverse effects. As shown in Table 1, biopharmaceutics is based on the physicochemical characteristics of the active drug substance, the desired drug product, and considerations of the anatomy and physiology of the human body (1). Inherent in the design of a suitable drug product is knowledge of the pharmacodynamics of the drug, including the desired onset time, duration, and intensity of clinical response, and the pharmacokinetics of the drug including absorption, distribution, elimination, and target drug concentration.

Thus, biopharmaceutics involves factors that influence the: 1) protection and stability of the drug within the drug product; 2) the rate of drug release from the

drug product; 3) the rate of dissolution of the drug at the absorption site; and 4) the availability of the drug at its site of action (Fig. 1).

BIOPHARMACEUTIC CONSIDERATIONS IN DRUG PRODUCT DESIGN

Drugs are generally given to a patient as a manufactured drug product (finished dosage form) that includes the active drug and selected ingredients (excipients) that make up the dosage form. Common pharmaceutical dosage forms include liquids, tablets, capsules, injections, suppositories, transdermal systems, and topical drug products. The formulation and manufacture of a drug product requires a thorough understanding of the biopharmaceutics.

Each route of drug application presents special biopharmaceutic considerations in drug product design (Table 2). Systemic drug absorption from an extravascular site is influenced by the anatomic and physiologic properties of the site and the physicochemical properties of the drug and the drug product. The anatomy, physiology, and the contents of the gastrointestinal tract (GI) are considered in the design of a drug product for oral administration. For example, considerations in the design of a vaginal tablet formulation for the treatment of a fungus infection include whether the ingredients are compatible with vaginal anatomy and physiology, whether the drug is systemically absorbed from the vagina and how the vaginal tablet is to be properly inserted and placed in the appropriate area for optimum efficacy. Requirements for an eye medication include pH, isotonicity, sterility, local irritation to the cornea, draining of the drug by tears, and concern for systemic drug absorption. An additional consideration might be the contact time of the medication with the cornea. Although, increased eye contact time might be achieved by an increase in viscosity of the ophthalmic solution, the patient may lose some visual acuity when a viscous product is administered. Biopharmaceutic considerations for a drug administered

Table 1 Biopharmaceutic considerations in drug product design

Active pharmaceutical ingredient (API)	Stability Solubility pH and pKa Crystalline form (polymorph) Excipient interaction and compatability	Impurities Salt form Particle size Complexation
Drug product	Type of drug product (capsule, tablet, solution, etc.) Immediate or modified release Dosage strength Bioavailability	Stability Excipients Manufacturing variables
Physiologic factors	Route of administration Permeation of drug across cell membranes Binding to macromolecules	Blood flow Surface area Biotransformation
Pharmacodynamic and pharmacokinetic considerations	Bioavailability Therapeutic objective Adverse reactions	Pharmacokinetics Dose Toxic effects
Manufacturing considerations	Production methodology and technology Quality control/quality assurance Specification of raw materials	Cost Stability testing
Patient considerations	Compliance, labeling, and product acceptance	Cost

Fig. 1 Scheme demonstrating the dynamic relationships among the drug, the product, and pharmacologic effect. (From Ref. 1.)

by intramuscular injection include, local irritation, drug dissolution, and drug absorption from the injection site.

Biopharmaceutic studies may be performed using *in vitro* or *in vivo* methods (Table 3). *In vitro* methods are useful (2–6) to understand the physico-chemical properties of the drug and drug product and to evaluate the quality of the manufacturing process. Ultimately, the drug must be studied *in vivo*, in humans to assess drug efficacy, including the pharmacodynamic, pharmacokinetic, therapeutic and toxic profiles. Drug dissolution, absorption, metabolism, and potential interaction with food and other components in the GI tract are major biopharmaceutic topics for research and regulatory considerations in drug development.

A drug given by intravenous administration is considered complete or 100% bioavailable because the drug is placed directly into the systemic circulation. By carefully choosing the route of drug administration and proper design of the drug product, drug bioavailability can be varied from rapid and complete systemic drug absorption to a slow, sustained rate of absorption or even virtually no absorption, depending on the therapeutic objective. Once the drug is systemically absorbed, normal physiologic processes for distribution and elimination occur, which usually is not influenced by the specific formulation of the drug. The rate of drug release from the product, and the rate of drug absorption, are important in determining the onset, intensity, and duration of drug action of the drug.

RATE-LIMITING STEPS IN ORAL DRUG ABSORPTION

Systemic drug absorption from a drug product consists of a succession of rate processes (Fig. 2). For solid oral, immediate release drug products (e.g., tablet, capsule), the rate processes include 1) disintegration of the drug product and subsequent release of the drug; 2) dissolution of the drug in an aqueous environment; and 3) absorption across cell membranes into the systemic circulation. In the

process of drug disintegration, dissolution, and absorption, the rate at which drug reaches the circulatory system is determined by the slowest step in the sequence.

The slowest step in a kinetic process is the rate-limiting step. Except for controlled release products, disintegration of a solid oral drug product is usually more rapid than drug dissolution and drug absorption. For drugs that have very poor aqueous solubility, the rate at which the drug dissolves (dissolution) is often the slowest step, and therefore exerts a rate-limiting effect on drug bioavailability. In contrast, for a drug that has a high aqueous solubility, the dissolution rate is rapid and the rate at which the drug crosses or permeates cell membranes is the slowest or rate-limiting step.

PHYSIOLOGIC FACTORS AFFECTING DRUG ABSORPTION

Passage of Drugs Across Cell Membranes

For systemic absorption, a drug must pass from the absorption site through or around one or more layers of cells to gain access into the general circulation. The permeability of a drug at the absorption site into the systemic circulation is intimately related to the molecular structure of the drug and the physical and biochemical properties of the cell membranes. For absorption into the cell, a drug must traverse the cell membrane. Transcellular absorption is the process of a drug movement across a cell. Some polar molecules may not be able to traverse the cell membrane, but instead, go through gaps or “tight junctions” between cells, a process known as paracellular drug absorption. Some drugs are probably absorbed by a mixed mechanism involving one or more processes.

Passive diffusion

Passive diffusion is the process by which molecules spontaneously diffuse from a region of higher concentration to a region of lower concentration. This process is passive because no external energy is expended. Drug

Table 2 Common routes of drug administration

Route	Bioavailability	Advantages	Disadvantages
Parenteral routes			
Intravenous bolus (IV)	Complete (100%) systemic drug absorption. Rate of bioavailability considered instantaneous.	Drug is given for immediate effect.	Increased chance for adverse reaction. Possible anaphylaxis.
Intravenous infusion (IV inf)	Complete (100%) systemic drug absorption.	Plasma drug levels more precisely controlled. May inject large fluid volumes.	Requires skill in insertion of infusion set.
Intramuscular injection (IM)	Rate of drug absorption controlled by infusion pump. Rapid from aqueous solution.	May use drugs with poor lipid solubility and/or irritating drugs. Easier to inject than intravenous injection.	Tissue damage at site of injection (infiltration, necrosis, or sterile abscess). Irritating drugs may be very painful.
Subcutaneous injection (SC)	Slow absorption from nonaqueous (oil) solutions. Prompt from aqueous solution.	Larger volumes may be used compared to subcutaneous solution. Generally, used for insulin injection.	Different rates of absorption depending upon muscle group injected and blood flow. Rate of drug absorption depends upon blood flow and injection volume.
Enteral Routes			
Buccal or sublingual (SL)	Slow absorption from repository formulations. Rapid absorption from lipid-soluble drugs.	No "first-pass" effects.	Some drug may be swallowed. Not for most drugs or drugs with high doses.
Oral (PO)	Absorption may vary. Generally slower absorption rate compared to IV bolus or IM injection.	Safest and easiest route of drug administration. May use immediate-release and modified-release drug products.	Some drugs may have erratic absorption, be unstable in the gastrointestinal tract, or be metabolized by liver prior to systemic absorption.
Rectal (PR)	Absorption may vary from suppository.	Useful when patient cannot swallow medication.	Absorption may be erratic. Suppository may migrate to different position.
Other routes			
Transdermal	More reliable absorption from enema (solution). Slow absorption, rate may vary.	Used for local and systemic effects.	Some patient discomfort.
Inhalation	Increased absorption with occlusive dressing. Rapid absorption. Total dose absorbed is variable.	Transdermal delivery system (patch) is easy to use. Used for lipid-soluble drugs with low dose and low MW. May be used for local or systemic effects.	Some irritation by patch or drug. Permeability of skin variable with condition, anatomic site, age, and gender. Type of cream or ointment base affects drug release and absorption. Particle size of drug determines anatomic placement in respiratory tract. May stimulate cough reflex. Some drug may be swallowed.

(From Ref. 1.)

Table 3 Examples of in vitro and in vivo biopharmaceutic studies

Biopharmaceutic studies (in vivo)	Bioavailability study	Measurement of drug in plasma, urine or other tissues
	Acute pharmacologic effect	Measurement of a pharmacodynamic effect, e.g., FEV ₁ , blood pressure, heart rate, skin blanching
Biopharmaceutic studies (in vitro)	Clinical study	Measurement of drug efficacy
	Drug release/dissolution	Measurement of the rate of drug dissolved under specified conditions
	Drug permeability	Use of CACO2 cells (an isolated colon cell line) are grown into membranes to study the intestinal permeability and gut metabolism of drugs.
	Drug biotransformation (metabolism)	Use of liver cells, homogenates or isolated cytochrome P450 isozymes to drug study biotransformation.

molecules move randomly forward and back across a membrane (Fig. 3). If the two regions have the same drug concentration, forward-moving drug molecules will be balanced by molecules moving back, resulting in no net transfer of drug. For a region that has a higher drug concentration, the number of forward-moving drug molecules will be higher than the number of backward-moving molecules, resulting in a transfer of molecules to the region with the lower drug concentration, as indicated by the big arrow. Flux is the rate of drug transfer and is represented by a vector to show its direction. Molecules tend to move randomly in all directions because molecules possess kinetic energy and constantly collide with each other in space. Only left and right molecule movements are shown in Fig. 3, because movement of

molecules in other directions would not result in concentration changes because of the limitation of the container wall.

Passive diffusion is the major transmembrane process for most drugs. The driving force for passive diffusion is the difference in drug concentrations on either side of the cell membrane. According to Fick's Law of Diffusion, drug molecules diffuse from a region of high drug concentration to a region of low drug concentration

$$dQ/dt = \{DAK/h\}(C_{GI} - C_p)$$

where dQ/dt = rate of diffusion; D = diffusion coefficient; K = partition coefficient; A = surface area

Fig. 2 Summary of processes involved following the oral administration of a drug in tablet or capsule form. (From Blanchard, J. Gastrointestinal absorption. II. Formulation factors affecting bioavailability. *Am. J. Pharm.* **1978**, *150*, 132–151.)

Fig. 3 Passive diffusion of molecules. Molecules in solution diffuse randomly in all directions. As molecules diffuse from left to right and vice versa (small arrows), a net diffusion from the high-concentration side to the low-concentration side results. This results in a net flux (J) to the right side. Flux is measured in mass per unit area (e.g., mg/cm^2). (From Ref. 1.)

of membrane; h = membrane thickness; and $C_{\text{GI}} - C_{\text{p}}$ = difference between the concentrations of drug in the GI tract and in the plasma.

Drug distributes rapidly into a large volume after entering the blood resulting in a very low plasma drug concentration with respect to the concentration at the site of drug administration. Drug is usually given in milligram doses, whereas plasma drug concentrations are often in the microgram per milliliter or nanogram per milliliter range. For drugs given orally, $C_{\text{GI}} \gg C_{\text{p}}$. A large concentration gradient is maintained driving drug molecules into the plasma from the GI tract.

As shown by Fick's Law of Diffusion, lipid solubility of the drug and the surface area and the thickness of the membrane influence the rate of passive diffusion of drugs. The partition coefficient, K , represents the lipid-water partitioning of a drug. More lipid soluble drugs have larger K values that theoretically increase the rate of systemic drug absorption. In practice, drug absorption is influenced by other physical factors of the drug, limiting its practical application of K . The surface area of the membrane through which the drug is absorbed directly influences the rate of drug absorption. Drugs may be absorbed from most areas of the GI tract. However, the duodenal area of the small intestine shows the most rapid drug absorption due to such anatomic features as villi and microvilli, which provide a large surface area. These villi are not found in such numbers in other areas of the GI tract.

The membrane thickness, h , is a constant at the absorption site but may be altered by disease. Drugs usually diffuse very rapidly into tissues through capillary cell membranes in the vascular compartments. In the brain, the capillaries are densely lined with glial cells creating a thicker lipid barrier (blood-brain barrier) causing a drug to diffuse more slowly into brain. In certain disease states (e.g., meningitis) the cell

membranes may be disrupted or become more permeable to drug diffusion.

Many drugs have lipophilic and hydrophilic substituents. More lipid soluble drug molecules traverse cell membranes more easily than less lipid-soluble (i.e., more water-soluble) molecules. For weak electrolyte drugs (i.e., weak acids, bases), the extent of ionization influences drug solubility and the rate of drug transport. Ionized drugs are more water soluble than nonionized drugs which are more lipid soluble. The extent of ionization of a weak electrolyte depends on the pK_a of the drug and the partition hypothesis (pH) of the medium in which the drug is dissolved. The Henderson and Hasselbalch equation describes the ratio of ionized (charged) to unionized form of the drug and is dependent on the pH conditions and the pK_a of the drug:

For weak acids,

$$\text{Ratio} = -\frac{(\text{salt})}{(\text{acid})} = \frac{(\text{A}^-)}{(\text{HA})} = 10^{(\text{pH}-\text{pK}_a)}$$

For weak bases,

$$\text{Ratio} = -(\text{base}) (\text{salt}) = (\text{RNH})_2 (\text{RNH}^{+3}) = 10^{(\text{pH}-\text{pK}_a)}$$

According to the pH , a weak acid (e.g., salicylic acid) should be rapidly absorbed from the stomach (pH 1.2) due to a favorable concentration gradient of the unionized (more lipid soluble) drug from the stomach to the blood, because practically all the drug in the blood compartment is dissociated (ionized) at pH 7.4. A weak base (e.g., quinidine) is highly ionized in acid pH and is poorly absorbed from the stomach. Although many drugs obey by the pH , in practice, the major site of absorption of most drugs is usually in the small intestine (duodenum) due presence of a large surface area and high blood flow.

The drug concentration on either side of a membrane is also influenced by the affinity of the drug for a tissue component, which prevents the drug from freely moving back across the cell membrane. For example, drug that binds plasma or tissue proteins causes the drug to concentrate in that region. Dicumarol and sulfonamides strongly bind plasma proteins; whereas, chlordane, a lipid-soluble insecticide, partitions and concentrates into adipose (fat) tissue. Tetracycline forms a complex with calcium and concentrates in the bones and teeth. Drugs may concentrate in a tissue due to a specific uptake or active transport process. Such processes have been demonstrated for iodide in thyroid tissue, potassium in the intracellular water, and certain catecholamines in adrenergic storage sites.

Fig. 4 Hypothetical carrier-mediated transport process. (From Ref. 1.)

Carrier-mediated transport

Theoretically, a lipophilic drug may pass through the cell or go around it. If drug has a low molecular weight and is lipophilic, the lipid cell membrane is not a barrier to drug diffusion and absorption. In the intestine, molecules smaller than 500 MW may be absorbed by paracellular drug absorption. Numerous specialized carrier-mediated transport systems are present in the body especially in the intestine for the absorption of ions and nutrients required by the body.

Active transport: Active transport is a carrier-mediated transmembrane process that is important for GI absorption of some drugs and also involved in the renal and biliary secretion of many drugs and metabolites. A carrier binds the drug to form a carrier–drug complex that shuttles the drug across the membrane and then dissociates the drug on the other side of the membrane (Fig. 4). Active transport is an energy-consuming system characterized by the transport of drug against a concentration gradient, that is, from regions of low drug concentrations to regions of high concentrations.

A drug may be actively transported, if the drug molecule structurally resembles a natural substrate that is actively transported. A few lipid-insoluble drugs that resemble natural physiologic metabolites (e.g., 5-fluorouracil) are absorbed from the GI tract by this process. Drugs of similar structure may compete for adsorption sites on the carrier. Because only a certain amount of carrier is available, the binding sites on the carrier may become saturated at high drug concentrations. In contrast, passive diffusion is not saturable.

Facilitated diffusion: Facilitated diffusion is a non-energy requiring, carrier-mediated transport system in which the drug moves along a concentration gradient (i.e., moves from a region of high drug concentration to a region of low drug concentration). Facilitated diffusion is saturable, structurally selective for the drug and shows competition kinetics for drugs of similar structure. Facilitated diffusion seems to play a very minor role in drug absorption.

Carrier-mediated intestinal transport: Various carrier mediated systems (transporters) are present at the intestinal brush border and basolateral membrane for

the absorption of specific ions and nutrients essential for the body. Many drugs are absorbed by these carriers because of the structural similarity to natural substrates. An intestinal transmembrane protein, *P*-Glycoprotein (*P*-Gp) appears to reduce apparent intestinal epithelial cell permeability from lumen to blood for various lipophilic or cytotoxic drugs. Other transporters are present in the intestines. For example, many oral cephalosporins are absorbed through the amino acid transporter.

Vesicular transport

Vesicular transport is the process of engulfing particles or dissolved materials by the cell. Pinocytosis refers to the engulfment of small solutes or fluid, whereas phagocytosis refers to the engulfment of larger particles or macromolecules generally by macrophages. Endocytosis and exocytosis are the processes of moving macromolecules into and out of a cell, respectively.

During pinocytosis or phagocytosis, the cell membrane invaginates to surround the material, and then engulfs the material into the cell. Subsequently, the cell membrane containing the material forms a vesicle or vacuole within the cell. Vesicular transport is the proposed process for the absorption of orally administered sabin polio vaccine and various large proteins. An example of exocytosis is the transport of a protein such as insulin from insulin-producing cells of the pancreas into the extracellular space. The insulin molecules are first packaged into intracellular vesicles, which then fuse with the plasma membrane to release the insulin outside the cell.

ORAL DRUG ABSORPTION

Physiologic Considerations

Drugs may be administered by various routes of administration (Table 2). Except for intravenous drug administration, drugs are absorbed into the systemic circulation from the site of administration and are greatly affected by conditions at the administration site.

Oral administration is the most common route of drug administration. Major physiologic processes in the GI system include secretion, digestion, and absorption. Secretion includes the transport of fluid, electrolytes, peptides, and proteins into the lumen of the alimentary canal. Enzymes in saliva and pancreatic secretions are involved in the digestion of carbohydrates and proteins. Other secretions such as mucus protect the linings of the lumen of the GI tract. Digestion is the breakdown of food

constituents into smaller structures in preparation for absorption. Both drug and food constituents are mostly absorbed in the proximal area (duodenum) of the small intestine. The process of absorption is the entry of constituents from the lumen of the gut into the body. Absorption may be considered as the net result of both lumen-to-blood and blood-to-lumen transport movements.

Drugs administered orally pass through various parts of the enteral canal including the oral cavity, esophagus, and various parts of the GI tract. Residues eventually exit the body through the anus. Drugs may be absorbed by passive diffusion from all parts of the alimentary canal including sublingual, buccal, GI, and rectal absorption. For most drugs, the optimum site for drug absorption after oral administration is the upper portion of the small intestine or duodenum region. The unique anatomy of the duodenum provides an immense surface area for the drug to passively diffuse (Table 4). In addition, the duodenal region is highly perfused with a network of capillaries, which helps to maintain a concentration gradient from the intestinal lumen and plasma circulation.

The total transit time, including gastric emptying, small intestinal transit, and colonic transit ranges from 0.4 to 5 days. Small intestine transit time (SITT) ranges from 3 to 4 h for most healthy subjects. If absorption is not completed by the time a drug leaves the small intestine, drug absorption may be erratic or incomplete. The small intestine is normally filled with digestive juices and liquids, keeping the lumen contents fluid. In contrast, the fluid in the colon is reabsorbed, and the lumen content in the colon is either semisolid or solid, making further drug dissolution erratic and difficult.

Gastrointestinal motility

Once the drug is given orally, the exact location and/or environment of the drug product within the GI tract is difficult to discern. GI motility tends to move the drug through the alimentary canal so that it may not stay at the absorption site. For drugs given orally, an anatomic absorption window may exist within the GI tract in which the drug is efficiently absorbed. Drugs contained in a nonbiodegradable controlled-release dosage form must be completely released into this absorption window prior to the movement of the dosage form into the large bowel. The transit time of the drug in the GI tract depends upon the pharmacologic properties of the drug, type of dosage form, and various physiologic factors. Physiologic movement of the drug within the GI tract depends upon whether the alimentary canal contains recently ingested food (digestive or fed state) or is in the fasted or interdigestive state.

Gastric emptying time

After oral administration, the swallowed drug rapidly reaches the stomach. Because the duodenum has the greatest capacity for the absorption of drugs from the GI tract, a delay in the gastric emptying time will slow the rate and possibly the extent of drug absorption from the duodenum, thereby prolonging the onset time for the drug. Drugs, such as penicillin, that are unstable in acid, may decompose if stomach emptying is delayed. Other drugs, (e.g., aspirin) may irritate the gastric mucosa during prolonged contact.

Factors that tend to delay gastric emptying include consumption of meals high in fat, cold beverages, and anticholinergic drugs. Liquids and small particles less than 1 mm are generally not retained in the stomach. These small particles are believed to be emptied due to a slightly higher basal pressure in the stomach over the duodenum. Different constituents of a meal will empty from the stomach at different rates. For example, liquids are generally emptied faster than digested solids from the stomach. Large particles, including tablets and capsules, are delayed from emptying for 3–6 h by the presence of food in the stomach. Indigestible solids empty very slowly, probably during the interdigestive phase, a phase in which food is not present and the stomach is less motile but periodically empties its content due to housekeeper wave contraction.

Intestinal motility

Normal peristaltic movements mix the contents of the duodenum, bringing the drug particles into intimate contact with the intestinal mucosal cells. The drug must have a sufficient time (residence time) at the absorption site for optimum absorption. In the case of high motility in the intestinal tract, as in diarrhea, the drug has a very brief residence time and less opportunity for adequate absorption.

Blood perfusion of the gastrointestinal tract

The blood flow is important in carrying the absorbed drug from the absorption site to the systemic circulation. A large network of capillaries and lymphatic vessels perfuse the duodenal region and peritoneum. The splanchnic circulation receives about 28% of the cardiac output and is increased after meals. Drugs are absorbed from the small intestine into the mesenteric vessels which flows to the hepatic-portal vein and then to the liver prior to reaching the systemic circulation. Any decrease in mesenteric blood flow, as in the case of congestive heart failure, will decrease the rate of systemic drug absorption from the intestinal tract.

Table 4 Drug absorption in the gastrointestinal tract

Anatomic area	Function	Affect on drug absorption
Oral cavity	Saliva, pH 7, contains ptyalin (salivary amylase), digests starches. Mucin, a glycoprotein, lubricates food and may interact with drugs.	Buccal and sublingual absorption occurs for lipid-soluble drugs.
Esophagus	The esophagus connects the pharynx and the cardiac orifice of the stomach. The pH is 5–6. The lower part of the esophagus ends with the esophageal sphincter, which prevents acid reflux from the stomach.	Tablets or capsules may lodge in this area, causing local irritation. Very little drug dissolution occurs in the esophagus.
Stomach	The fasting stomach pH is about 2 to 6. In the fed state, the stomach pH is about 1.5 to 2, due to hydrochloric acid secreted by parietal cells. Stomach acid secretion is stimulated by gastrin and histamine. Mixing is intense and pressurized in the antral part of the stomach, a process of breaking down large food particles described as antral milling. Food and liquid are emptied by opening the pyloric sphincter into the duodenum.	Drugs are not efficiently absorbed in the stomach. Basic drugs are solubilized rapidly in acid. Stomach emptying influences the time for drug reaching the small intestine. The food content and osmolality influenced by stomach emptying. Fatty acids delay gastric emptying. High-density foods generally are emptied more slowly from the stomach.
Duodenum	A common duct from the pancreas and gall bladder enters the duodenum. Duodenal pH is 6 to 6.5 due to the presence of bicarbonate that neutralizes the acidic chyme emptied from the stomach. The pH is optimum for enzymatic digestion of protein and peptide food. Pancreatic juice containing enzymes is secreted into the duodenum from the bile duct. Trypsin, chymotrypsin, and carboxypeptidase are involved in the hydrolysis of proteins into amino acids. Amylase is involved in the digestion of carbohydrates. Pancreatic lipase secretion hydrolyzes fats into fatty acids.	The main site for drug absorption. An immense surface area for the passive diffusion of drug to due to the presence of villi and microvilli forming a brush border. A high blood perfusion maintains a drug concentration gradient from the intestinal lumen and plasma circulation. The complex fluid medium in the duodenum dissolves many drugs with limited aqueous solubility. Ester prodrugs are hydrolyzed during absorption. Proteolytic enzymes degrade many protein drugs in the duodenum, preventing adequate absorption. Acid drugs dissolve in the alkaline pH. Bile secretion helps to dissolve fats and hydrophobic drugs
Jejunum	The jejunum is the middle portion of the small intestine in between the duodenum and the ileum. Digestion of protein and carbohydrates continues after receiving pancreatic juice and bile in the duodenum, this portion of the small intestine generally has less contraction than the duodenum and is preferred for in vivo drug absorption studies.	Drugs generally absorbed by passive diffusion.
Ileum	The ileum, pH about 7, with the distal part as high as 8, is the terminal part of the small intestine and has fewer contractions than the duodenum. The ileocecal valve separates the small intestine with the colon.	Drugs generally absorbed by passive diffusion.
Colon	The colon, pH 5.5–7, is lined with mucin functioning as lubricant and protectant. The colon contains both aerobic and anaerobic micro-organisms that may metabolize some drugs. Crohn's disease affects the colon and thickens the bowel wall. The microflora may also become more anaerobic. Absorption of clindamycin and propranolol are increased, whereas other drugs have reduced absorption with this disease (Rubinstein et al. 1988).	Very limited drug absorption due to the lack of microvilli and the more viscous and semisolid nature of the lumen contents. A few drugs such as theophylline and metoprolol are absorbed in this region. Drugs that are absorbed well in this region are good candidates for an oral sustained-release dosage form.

(Continued)

Table 4 Drug absorption in the gastrointestinal tract (*Continued*)

Anatomic area	Function	Affect on drug absorption
Rectum	<p>The rectum is about 15 cm long, ending at the anus.</p> <p>In the absence of fecal material, the rectum has a small amount of fluid, (about 2 m) with a pH about 7.</p> <p>The rectum is perfused by the superior, middle, and inferior hemorrhoidal veins. The inferior hemorrhoidal vein (closest to the anal sphincter) and the middle hemorrhoidal vein feed into the vena cava and back to the heart. The superior hemorrhoidal vein joins the mesenteric circulation, which feeds into the hepatic portal vein and then to the liver.</p>	<p>Drug absorption may be variable depending upon the placement of the suppository or drug solution within the rectum. A portion of the drug dose may be absorbed via the lower hemorrhoidal veins, from which the drug feeds directly into the systemic circulation; some drug may be absorbed via the superior hemorrhoidal veins, which feeds into the mesenteric veins to the hepatic portal vein to the liver, and metabolized prior to systemic absorption.</p>

Some drugs may be absorbed into the lymphatic circulation through the lacteal or lymphatic vessels under the microvilli. Absorption of drugs through the lymphatic system bypasses the first-pass effect due to liver metabolism, because drug absorption through the hepatic portal vein is avoided. The lymphatics are important in the absorption of dietary lipids and may be partially responsible for the absorption for some lipophilic drugs such as bleomycin or aclarubicin which may dissolve in chylomicrons and be systemically absorbed via the lymphatic system.

Effect of food and other factors on GI drug absorption

Digested foods may affect intestinal pH and solubility of drugs. Food effects are not always predictable. The absorption of some antibiotics (e.g., penicillin, tetracycline) is decreased with food, whereas other drugs (e.g., griseofulvin) are better absorbed when given with food containing a high fat content. Food in the GI lumen stimulates the flow of bile. Bile contains bile acids. Bile acids are surfactants are involved in the digestion and solubilization of fats, and increases the solubility of fat-soluble drugs through micelle formation. For some basic drugs (e.g., cinnarizine) with limited aqueous solubility, the presence of food in the stomach stimulates hydrochloric acid secretion, which lowers the pH, causing more rapid dissolution of the drug and better absorption.

Generally, the bioavailability of drugs is better in patients in the fasted state and with a large volume of water (Fig. 5). However, to reduce GI mucosal irritation, drugs such as erythromycin, iron salts, aspirin, and nonsteroidal anti-inflammatory agents (NSAIDs) are given with food. The rate of absorption for these drugs may be reduced in the presence of food, but the extent of absorption may be the same.

The drug dosage form may also be affected by food. For example, enteric-coated tablets may stay in the stomach for a longer period of time because food delays stomach emptying. If the enteric-coated tablet does not reach the duodenum rapidly, drug release and subsequent systemic drug absorption are delayed. In contrast, enteric-coated beads or microparticles disperse in the stomach, are less affected by food, and demonstrate more consistent drug absorption from the duodenum.

Food may also affect the integrity of the dosage form, causing an alteration in the release rate of the drug. For example, theophylline bioavailability from Theo-24 controlled-release tablets is much more rapid (7) when given to a subject in the fed rather than fasted state (Fig. 6).

Some drugs, such as ranitidine, cimetidine, and dipyridamole, after oral administration produce a blood concentration curve consisting of two peaks. This double-peak phenomenon is generally observed after the administration of a single dose to fasted patients. The rationale for the double-peak phenomenon has been attributed to variability in stomach emptying, variable intestinal motility, presence of food, enterohepatic recycling, or failure of a tablet dosage form. For a drug with high water solubility, dissolution of the drug occurs in the stomach, and partial emptying of the drug into the duodenum will result in the first absorption peak. A delay in stomach emptying results in a second absorption peak as the remainder of the dose is emptied into the duodenum.

Diseases such as Crohn's disease that alter GI physiology and corrective surgery involving peptic ulcer, antrectomy with gastroduodenostomy and selective vagotomy may potentially affect drug absorption. Drug absorption may be unpredictable in many disease conditions. Drugs or nutrients or both may also affect the absorption of other drugs. For example, propantheline

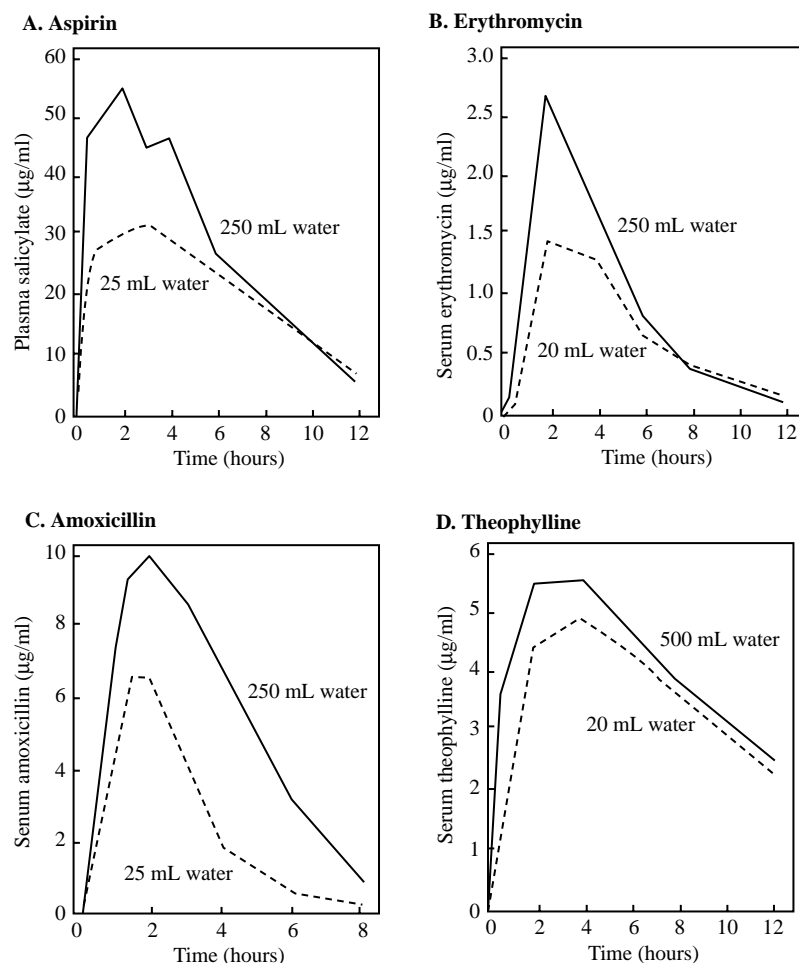

Fig. 5 Mean plasma or serum drug levels in healthy, fasting human volunteers ($n = 6$ in each case) who received single oral doses of aspirin (650 mg) tablets, erythromycin stearate (500 mg) tablets, amoxicillin (500 mg) capsules, and theophylline (260 mg) tablets, together with large. (From Welling P.G.; Drug Bioavailability and Its Clinical Significance. *Progress in Drug Metabolism*, Vol. 4; Bridges K.W.; Chassea, VD LF. Eds.; Wiley; London, 1980.)

bromide is an anticholinergic drug that slows stomach emptying and motility of the small intestine and may reduce stomach acid secretion. Grapefruit juice was found to increase the plasma level of many drugs due to inhibition of their metabolism in the liver.

PHARMACEUTICAL FACTORS AFFECTING DRUG BIOAVAILABILITY

Biopharmaceutic considerations in the design and manufacture of a drug product to deliver the active drug with the desired bioavailability characteristics include: 1) the type of drug product (e.g., solution,

suspension, suppository), 2) the nature of the excipients in the drug product, 3) the physicochemical properties of the drug molecule, and 4) the route of drug administration.

Disintegration

Immediate release, solid oral drug products must rapidly disintegrate into small particles and release the drug. The United States Pharmacopoeia (USP) describes an official tablet disintegration test. The process of disintegration does not imply complete dissolution of the tablet and/or the drug. Complete disintegration is defined by the USP as "that state in which any residue of the tablet, except fragments of insoluble coating, remaining on the screen of

Fig. 6 Theophylline serum concentration in an individual subject after a single 1500 mg dose of Theo-24 taken during fasting, period during which this patient experienced nausea, repeated vomiting, or severe throbbing headache. The pattern of drug release during the food regimen is consistent with “dose-dumping.” (From Ref. 7.)

the test apparatus in the soft mass have no palpably firm core.” The USP provides specifications for uncoated tablets, plain coated tablets, enteric tablets, buccal tablets, and sublingual tablets. Exempted from USP disintegration tests are troches, tablets which are intended to be chewed, and drug products intended for sustained release or prolonged or repeat action.

Disintegration tests allow for precise measurement of the formation of fragments, granules, or aggregates from solid dosage forms, but do not provide information on the dissolution rate of the active drug. The disintegration test serves as a component in the overall quality control of tablet manufacture.

Dissolution

Dissolution is the process by which a chemical or drug becomes dissolved in a solvent. In biologic systems, drug dissolution in an aqueous medium is an important prior condition of systemic absorption. The rate at which drugs with poor aqueous solubility dissolve from an intact or disintegrated solid dosage form in the GI tract often controls the rate of systemic absorption of the drug. Thus, dissolution tests are discriminating of formulation factors that may affect drug bioavailability.

As the drug particle dissolves, a saturated solution (stagnant layer) is formed at the immediate surface around the particle. The dissolved drug in the saturated solution gradually diffuses to the surrounding regions. The overall rate of drug dissolution may be described by the Noyes–Whitney equation which models drug dissolution in terms

of the rate of drug diffusion from the surface to the bulk of the solution. In general, drug concentration at the surface is assumed to be the highest possible, i.e., the solubility of the drug in the dissolution medium. The drug concentration C is the homogeneous concentration in the bulk solution which is generally lower than that in the stagnant layer immediate to the surface of the solid. The decrease in concentration across the stagnant layer is called the diffusion gradient

$$dC/dt = DA(CS - C)h$$

where, dC/dt = rate of drug dissolution, D = diffusion rate constant, A = surface area of the particle, CS = drug concentration in the stagnant layer, C = drug concentration in the bulk solvent, and h = thickness of the stagnant layer.

The rate of dissolution, $(dC/dt) \times (1/A)$, is the amount of drug dissolved per unit area per time (e.g., g/cm² per min).

The Noyes–Whitney equation shows that dissolution rate is influenced by the physicochemical characteristics of the drug, the formulation, and the solvent. In addition, the temperature of the medium also affects drug solubility and dissolution rate.

PHYSICOCHEMICAL NATURE OF THE DRUG

Solubility, pH, and Drug Absorption

The natural pH environment of the GI tract varies from acidic in the stomach to slightly alkaline in the small intestine. Drug solubility may be improved with the addition of acidic or basic excipients. Solubilization of aspirin, for example, may be increased by the addition of an alkaline buffer. Controlled release drug products are nondisintegrating dosage forms. Buffering agents may be added to slow or modify the release rate of a fast-dissolving drug in the formulation of a controlled release drug product. The buffering agent is released slowly rather than rapidly so that the drug does not dissolve immediately in the surrounding GI fluid. Intravenous drug solutions are difficult to prepare with drugs that have poor aqueous solubility. Drugs that are physically or chemically unstable may require special excipients, coating or manufacturing process to protect the drug from degradation.

Stability, pH, and Drug Absorption

The pH-stability profile is a plot of reaction rate constant for drug degradation versus pH and may help to predict if

some of the drug will decompose in the GI tract. The stability of erythromycin is pH-dependent. In acidic medium, erythromycin decomposition occurs rapidly, whereas at neutral or alkaline pH the drug is relatively stable. Consequently, erythromycin tablets are enteric coated to protect against acid degradation in the stomach. In addition, less soluble erythromycin salts that are more stable in the stomach have been prepared.

Particle Size and Drug Absorption

The effective surface area of the drug is increased enormously by a reduction in the particle size. Because drug dissolution is thought to take place at the surface of the solute, the greater the surface area, the more rapid the rate of drug dissolution. The geometric shape of the drug particle also affects the surface area, and during dissolution the surface is constantly changing. In dissolution calculations, the solute particle is usually assumed to have retained its geometric shape.

Particle size and particle size distribution studies are important for drugs that have low water solubility. Particle size reduction by milling to a micronized form increased the absorption of low aqueous solubility drugs such as griseofulvin, nitrofurantoin, and many steroids. Smaller particle size results in an increase in the total surface area of the particles, enhances water penetration into the particles, and increases the dissolution rates. With poorly soluble drugs, a disintegrant may be added to the formulation to ensure rapid disintegration of the tablet and release of the particles.

Polymorphic Crystals, Solvates, and Drug Absorption

Polymorphism refers to the arrangement of a drug in various crystal forms (polymorphs). Polymorphs have the same chemical structure but different physical properties, such as solubility, density, hardness, and compression characteristics. Some polymorphic crystals may have much lower aqueous solubility than the amorphous forms, causing a product to be incompletely absorbed. Chloramphenicol (9), for example, has several crystal forms, and when given orally as a suspension, the drug concentration in the body depended on the percentage of β -Polymorph in the suspension. The β -form is more soluble and better absorbed (Fig. 7). In general, the crystal form that has the lowest free energy is the most stable polymorph. Polymorphs that are metastable may convert to a more stable form over time. A crystal form change may cause problems in manufacturing the product. For example, a

Fig. 7 Comparison of mean blood serum levels obtained with chloramphenicol palmitate suspensions containing varying ratios of α and β polymorphs, following single oral dose equivalent. (From Ref. 9.)

change in crystal structure of the drug may cause cracking in a tablet or even prevent a granulation to be compressed into a tablet requiring reformulation of the product. Some drugs interact with solvent during preparation to form a crystal called solvate. Water may form a special crystal with drugs called hydrates, for example, erythromycin forms different hydrates (8) which may have quite different solubility compared to the anhydrous form of the drug (Fig. 8). Ampicillin trihydrate, for example, was reported

Fig. 8 Dissolution behavior of erythromycin dihydrate, monohydrate, and anhydrate in phosphate buffer (pH 7.5) at 37°C. (From Ref. 8.)

Table 5 Common excipients used in solid drug products

Excipient	Property in dosage form
Lactose	Diluent
Dibasic calcium phosphate	Diluent
Starch	Disintegrant, diluent
Microcrystalline cellulose	Disintegrant, diluent
Magnesium stearate	Lubricant
Stearic acid	Lubricant
Hydrogenated vegetable oil	Lubricant
Talc	Lubricant
Sucrose (solution)	Granulating agent
Polyvinyl pyrrolidone (solution)	Granulating agent
Hydroxypropylmethylcellulose	Tablet-coating agent
Titanium dioxide	Combined with dye as colored coating
Methylcellulose	Coating or granulating agent
Cellulose acetate phthalate	Enteric coating agent

(From Ref. 1.)

to be less absorbed than the anhydrous form of ampicillin due to faster dissolution of the latter.

FORMULATION FACTORS AFFECTING DRUG DISSOLUTION

Excipients are pharmacodynamically inactive substances that are added to a formulation to provide certain functional properties to the drug and dosage form. Excipients may be added to improve the compressibility of the active drug, stabilize the drug from degradation, decrease gastric irritation, control the rate of drug absorption from the absorption site, increase drug bioavailability, etc. Some excipients used in the

Table 6 Common excipients used in oral liquid drug products

Excipient	Property in dosage form
Sodium carboxymethylcellulose	Suspending agent
Tragacanth	Suspending agent
Sodium alginate	Suspending agent
Xanthan gum	Thixotropic suspending agent
Veegum	Thixotropic suspending agent
Sorbitol	Sweetener
Alcohol	Solubilizing agent, preservative
Propylene glycol	Solubilizing agent
Methyl propylparaben	Preservative
Sucrose	Sweetener
Polysorbates	Surfactant
Sesame oil	For emulsion vehicle
Corn oil	For emulsion vehicle

(From Ref. 1.)

manufacture of solid and liquid drug products are listed in Tables 5 and 6. For solid oral dosage forms such as compressed tablets, excipients may include 1) diluent (e.g., lactose), 2) disintegrant (e.g., starch), 3) lubricant (e.g., magnesium stearate), and 4) other components such as binding and stabilizing agents. When improperly used in the formulation, excipients may alter drug bioavailability and possibly pharmacodynamic activity.

Excipients may affect the drug dissolution rate by altering the medium in which the drug is dissolving or by reacting with the drug itself. Some common manufacturing problems that affect drug dissolution and bioavailability are listed in Table 7. For example,

Table 7 Effect of excipients on the pharmacokinetic parameters of oral drug product^a

Excipients	Example	k_a	t_{max}	AUC
Disintegrants	Avicel, Explotab	↑	←	↑/—
Lubricants	Talc, hydrogenated vegetable oil	←	↑	←/—
Coating agent	Hydroxypropylmethyl cellulose	—	—	—
Enteric coat	Cellulose acetate phthalate	←	↑	←/—
Sustained-release agents	Methylcellulose, ethylcellulose	←	↑	←/—
Sustained-release agents (waxy agents)	Castorwax, Carbowax	←	↑	←/—
Sustained-release agents (gum/viscous)	Veegum, Keltrol	←	↑	←/—

^aThis may be concentration and drug dependent.

↑ = Increase, ← = decrease, — = no effect. k_a = absorption rate constant, t_{max} = time for peak drug concentration in plasma, AUC = area under the plasma drug concentration time curve.

(From Ref. 1.)

suspending agents increase the viscosity of the drug vehicle, but may decrease the drug dissolution rate from the suspension. An excessive quantity of magnesium stearate (a hydrophobic lubricant) in the formulation may retard drug dissolution and slow the rate of drug absorption. The total amount of drug absorbed may also be reduced. To prevent this problem, the lubricant level should be decreased or a different lubricant selected. Sometimes, increasing the amount of disintegrant may overcome the retarding effect of lubricants on dissolution. However, with some poorly soluble drugs an increase in disintegrant level has little or no effect on drug dissolution because the fine drug particles are not wetted. The general influence of some common excipients on drug bioavailability parameters for typical oral drug products is summarized in Table 7.

Excipients may enhance or diminish the rate and extent of systemic drug absorption. Excipients that increase the aqueous solubility of the drug generally increase the rate of drug dissolution and absorption. For example, sodium bicarbonate in the formulation may change the pH of the medium surrounding the active drug substance. Aspirin, a weak acid, in an alkaline medium will form a water-soluble salt in which the drug rapidly dissolves. This process is known as dissolution in a reactive medium. The solid drug dissolves rapidly in the reactive solvent surrounding the solid particle. As the dissolved drug molecules diffuse outward into the bulk solvent, the drug may precipitate out of solution with a very fine particle size. The small particles have enormous collective surface area and disperse and redissolve readily for more rapid absorption on contact with the mucosal surface.

Excipients may interact directly with the drug to form a water-soluble or water-insoluble complex. If tetracycline is formulated with calcium carbonate, an insoluble complex of calcium tetracycline is formed that has a slow rate of dissolution and poor absorption.

Excipients may increase the retention time of the drug in the GI tract and therefore increase the amount of drug absorbed. Excipients may act as carriers to increase drug diffusion across the intestinal wall. The addition of surface-active agents may increase wetting as well as solubility of drugs. In contrast, many excipients may retard drug dissolution and thus reduce drug absorption.

Shellac used as a tablet coating, upon aging, can slow the drug dissolution rate. Surfactants may affect drug dissolution in an unpredictable fashion. Low concentrations of surfactants lower the surface tension and increase the rate of drug dissolution, whereas higher concentrations of surfactants tend to form micelles with

the drug and thus decrease the dissolution rate. High tablet compression without sufficient disintegrant may cause poor disintegration in vivo of a compressed tablet.

IN VITRO DISSOLUTION TESTING

A dissolution test in vitro measures the rate and extent of dissolution of the drug in an aqueous medium in the presence of one or more excipients contained in the drug product. A potential bioavailability problem may be uncovered by a suitable dissolution method. The optimum dissolution testing conditions differ with each drug formulation. Different agitation rates, different medium (including different pH), and different dissolution apparatus should be tried to distinguish which dissolution method is optimum for the drug product and discriminating for drug formulation changes. The appropriate dissolution test condition for the drug product is then used to determine acceptable dissolution specifications.

The size and shape of the dissolution vessel may affect the rate and extent of dissolution. For example, the vessel may range in size from several milliliters to several liters. The shape may be round-bottomed or flat, so that the tablet might lie in a different position in different experiments. The amount of agitation and the nature of the stirrer affect the dissolution rate. Stirring rates must be controlled, and specifications differ between drug products. Low stirring rates (50–100 rpm) are more discriminating of formulation factors affecting dissolution than higher stirring rates. The temperature of the dissolution medium must be controlled and variations in temperature must be avoided. Most dissolution tests are performed at 37°C.

The nature of the dissolution medium, the solubility of the drug and the amount of drug in the dosage form will affect the dissolution test. The dissolution medium should not be saturated by the drug. Usually, a volume of medium larger than the amount of solvent needed to completely dissolve the drug is used in such tests. The usual volume of the medium is 500–1000 ml. Drugs that are not very water soluble may require use of a very-large-capacity vessel (up to 2000 ml) to observe significant dissolution. Sink conditions is a term referring to an excess volume of medium that allows the solid drug to continuously dissolve. If the drug solution becomes saturated, no further net drug dissolution will take place. According to the USP, “the quantity of medium used should be not less than three times that required to form a saturated solution of the drug substance.”

Which medium is best is a matter of considerable controversy. The preferred dissolution medium in USP dissolution tests is deaerated water or if substantiated by the solubility characteristics of the drug or formulation, a buffered aqueous solution (typically pH 4–8) or dilute HCl may be used. The significance of deaeration of the medium should be determined. Various investigators have used 0.1 N HCl, 0.01 N HCl, phosphate buffer, simulated gastric juice, water, and simulated intestinal juice, depending on the nature of the drug product and the location in the GI tract where the drug is expected to dissolve. No single apparatus and test can be used for all drug products. Each drug product must be tested individually with the dissolution test that best correlates to in vivo bioavailability.

The dissolution test usually states that a certain percentage of the labeled amount of drug in the drug product must dissolve within a specified period of time. In practice, the absolute amount of drug in the drug product may vary from tablet to tablet. Therefore, a number of tablets from each lot are usually tested to get a representative dissolution rate for the product. The USP provides several official (compendia) methods for carrying out dissolution tests of tablets, capsules and other special products such as transdermal preparations. The selection of a particular method for a drug is usually specified in the monograph for a particular drug product.

BIOAVAILABILITY AND BIOEQUIVALENCE

Bioavailability and bioequivalence may be determined directly using plasma drug concentration vs. time profiles, urinary drug excretion studies, measurements of an acute pharmacologic effect, clinical studies, or in vitro studies. Bioavailability studies are performed for both approved active drug ingredients or therapeutic moieties not yet approved for marketing by the FDA. New formulations of active drug ingredients or therapeutic moieties must be approved, prior to marketing, by the FDA. In approving a drug product for marketing, the FDA must ensure that the drug product is safe and effective for its labeled indications for use. To ensure that the drug product meets all applicable standards of identity, strength, quality, and purity, the FDA requires bioavailability/pharmacokinetic studies and where necessary bioequivalence studies for all drug products.

For unmarketed drugs which do not have full New Drug Application (NDA) approval by the FDA, in vivo bioavailability studies must be performed on the

drug formulation proposed for marketing. Essential pharmacokinetic parameters of the active drug ingredient or therapeutic moiety is also characterized. Essential pharmacokinetic parameters include the rate and extent of systemic absorption, elimination half-life, and rates of excretion and metabolism should be established after single- and multiple-dose administration. Data from these in vivo bioavailability studies are important to establish recommended dosage regimens and to support drug labeling.

In vivo bioavailability studies are performed also for new formulations of active drug ingredients or therapeutic moieties that have full NDA approval and are approved for marketing. The purpose of these studies is to determine the bioavailability and characterize the pharmacokinetics of the new formulation, new dosage form, or new salt or ester relative to a reference formulation. After the bioavailability and essential pharmacokinetic parameters of the active ingredient or therapeutic moiety are established, dosage regimens may be recommended in support of drug labeling.

Bioequivalent Drug Products

Bioequivalent drug products are pharmaceutical equivalents whose bioavailability (i.e., rate and extent of systemic drug absorption) does not show a significant difference when administered at the same molar dose of the therapeutic moiety under similar experimental conditions, either single or multiple dose. Some pharmaceutical equivalents or may be equivalent in the extent of their absorption but not in their rate of absorption and yet may be considered bioequivalent because such differences in the rate of absorption are intentional and are reflected in the labeling, are not essential to the attainment of effective body drug concentrations on chronic use, or are considered medically insignificant for the particular drug product studied [21 CFR 320.1(e)].

Generic Drug Products

A generic drug product is considered bioequivalent to the reference listed drug product (generally the currently marketed, brand-name product with a full (NDA) approved by the FDA) if both products are pharmaceutical equivalents and its rate and extent of systemic drug absorption (bioavailability) do not show a statistically significant difference when administered in the same dose of the active ingredient, in the same chemical form, in a similar dosage form, by the same route of administration, and under the same experimental conditions.

Pharmaceutical equivalents are drug products that contain the same therapeutically active drug ingredient(s), same salt, ester, or chemical form; are of the same dosage form; and are identical in strength and concentration and route of administration. Pharmaceutical equivalents may differ in characteristics such as shape, scoring configuration, release mechanisms, packaging, and excipients (including colors, flavoring, preservatives).

Therapeutic equivalent drug products are pharmaceutical equivalents that can be expected to have the same clinical effect and safety profile when administered to patients under the same conditions specified in the labeling. Therapeutic equivalent drug products have the following criteria: 1) The products are safe and effective; 2) The products are pharmaceutical equivalents containing the same active drug ingredient in the same dosage form, given by the same route of administration, meet compendia or other applicable standards of strength, quality, purity, and identity and meet an acceptable in vitro standard; 3) The drug products are bioequivalent in that they do not present a known potential problem and are shown to meet an appropriate bioequivalence standard; 4) The drug products are adequately labeled; 5) The drug products are manufactured in compliance with current good manufacturing practice (GMP) regulations.

The generic drug product requires an abbreviated new drug application (ANDA) for approval by the FDA and may be marketed after patent expiration of the reference listed drug product. The generic drug product must be a therapeutic equivalent to the Reference drug product but may differ in certain characteristics including shape, scoring configuration, packaging, and excipients (includes colors, flavors, preservatives, expiration date, and minor aspects of labeling).

Pharmaceutical alternatives are drug products that contain same therapeutic moiety but are different salts, esters or complexes (e.g., tetracycline hydrochloride versus tetracycline phosphate) or are different dosage forms (e.g., tablet versus capsule; immediate release dosage form versus controlled release dosage form) or strengths.

In summary, clinical studies are useful in determining the safety and efficacy of the drug product. Bioavailability studies are used to define the affect of changes in the physico chemical properties of the drug substance and the affect of the drug product (dosage form) on the pharmacokinetics of the drug; whereas, bioequivalence studies are used to compare the bioavailability of the same drug (same salt or ester) from various drug products. If the drug products are bioequivalent and therapeutically equivalent, then the

clinical efficacy and safety profile of these drug products are assumed to be similar and may be substituted for each other.

DRUG PRODUCT PERFORMANCE IN VITRO AS A MEASURE OF IN VIVO DRUG BIOAVAILABILITY

The best measure of a drug product's performance is to give the drug product to human volunteers or patients and then determine the in vivo bioavailability of the drug using a pharmacokinetic or clinical study. For some well characterized drug products and for certain drug products where bioavailability is self-evident (e.g., sterile solutions for injection), in vivo bioavailability studies may be unnecessary. In these cases, the performance of the drug product in vitro is used as a surrogate to predict the in vivo drug bioavailability. Because these products have predictable in vivo performance as judged by the in vitro characterization of the drug and drug product, the FDA may waive the requirement for performing an in vivo bioavailability study (Table 8).

Drug Products for which Bioavailability is Self-Evident

Drug bioavailability from a true solution is generally considered self-evident. Thus, sterile solutions, lyophilized powders for reconstitution, ophthalmic solutions do not need bioequivalence studies but still must be manufactured according to current GMPs. However, highly viscous solutions may have bioavailability problems due to slow diffusion of the active drug.

In Vitro–In Vivo Correlation (IVIVC)

In vitro bioavailability data may be used to predict the performance of a dosage provided that the dissolution method selected is appropriate for the solid oral dosage form and prior information has been collected showing that the dissolution method will result in optimum drug absorption from the drug product. In general, IVIVC is best for well absorbed drugs for which the dissolution rate is the rate-limiting step. Some drugs are poorly absorbed and dissolution is not predictive of absorption (1). The objectives of IVIVC are to use rate of dissolution as a discriminating (i.e., sensitive to changes in formulation or manufacturing process), as an aid in setting dissolution specifications. When properly applied, IVIVC may be used to facilitate the evaluation

Table 8 Examples of drug products for which in vivo bioavailability studies may be waived

Condition	Example	Comment
Drug products for which bioavailability is self-evident	Drug solution (e.g., parenteral ophthalmic, oral solutions)	Drug bioavailability from a true solution is considered self-evident. However, highly viscous solutions may have bioavailability problems.
In vivo–in vitro correlation (IVIVC)	Modified release drug products	The dissolution of the drug from the drug product in vitro must be highly correlated to the in vivo bioavailability of the drug.
Biopharmaceutic classification (BCS) system	Immediate release solid oral drug products	Drug must be a highly soluble and highly permeable substance that is in a rapidly dissolving dosage form.
Biowaiver	Drug product containing a lower dose strength	Drug product is in the same dosage form, but lower strength and is proportionally similar in its active and inactive ingredients.

of drug products with manufacturing changes including minor changes in formulation, equipment, process, manufacturing site, and batch size. (see section on SUPAC) (2, 3, 10).

Three levels of IVIVC are generally recognized by the FDA (10). Level A correlation is usually estimated by deconvolution followed by comparison of the fraction of drug absorbed to the fraction of drug dissolved. A correlation of this type is the highest level of correlation and best predictor of bioavailability from the dosage form. A Level A correlation is generally linear and represents a point-to-point relationship between in vitro dissolution rate and the in vivo input rate. The Level A correlation should predict the entire in vivo time course from the in vitro dissolution data. Level B correlation utilizes the principles of statistical moment analysis. Various dissolution IVIVC methods were discussed by Shargel and Yu in 1985, 1993, 1999 (1). The mean in vitro dissolution time is compared to either the mean residence time or the mean in vivo dissolution time. Level B correlation, like Level A correlation, uses all of the in vitro and in vivo data but is not considered to be a point-to-point correlation and does not uniquely reflect the actual in vivo plasma level curve, since several different in vivo plasma level-time curves will produce similar residence times. A Level C correlation is the weakest IVIVC and establishes a single point relationship between a dissolution parameter (e.g., time for 50% of drug to dissolve, or percent drug dissolved in two hours, etc.) and a pharmacokinetic parameter (e.g., AUC, C_{max}, T_{max}). Level C correlation does not reflect the complete shape of the plasma drug concentration-time curve of dissolution profile.

BIOPHARMACEUTICS CLASSIFICATION SYSTEM (BCS)

The FDA may waive the requirement for performing an in vivo bioavailability or bioequivalence study for certain immediate release solid oral drug products that meets very specific criteria, namely, the permeability, solubility, and dissolution of the drug. These characteristics include the in vitro dissolution of the drug product in various media, drug permeability information, and assuming ideal behavior of the drug product, drug dissolution and absorption in the GI tract. For regulatory purpose, drugs are classified according to BCS in accordance the solubility, permeability and dissolution characteristics of the drug (FDA Draft Guidance for Industry, January, 1999, see FDA website for guidance) (11). Based on drug solubility and permeability, Amidon et al. (10, 12) recommended the following BCS in 1995 (Table 9).

This classification can be used as a basis for setting in vitro dissolution specifications and can also provide a basis for predicting the likelihood of achieving a successful in IVIVC. The solubility of a drug is determined by dissolving the highest unit dose of the drug in 250 ml of buffer adjusted between pH 1.0 and 8.0. A drug substance is considered highly soluble when the dose/solubility volume of solution are less than or equal to 250 ml. High-permeability drugs are generally those with an extent of absorption that is greater than 90%.

Solubility

An objective of the BCS approach is to determine the equilibrium solubility of a drug under approximate

Table 9 Biopharmaceutics classification system (BCS)

Condition	Comments
Solubility	A drug substance is considered highly soluble when the highest dose strength is soluble in 250 ml or less of water over a pH range of 1–8.
Dissolution	An immediate release (IR) drug product is considered rapidly dissolving when not less than 85% of the label amount of the drug substance dissolves within 30 min using the USP apparatus I at 100 rpm (or apparatus II at 50 rpm) in a volume of 900 ml or less. ^a
Permeability	A drug substance is considered highly permeable when the extent of absorption in humans is to be >90% of an administered dose based on mass balance determination.

^aMedia include: acidic media (e.g., 0.1 N HCl) or simulated gastric fluid, USP without enzymes, pH 4.5 buffer and pH 6.8 buffer of simulated intestinal fluid, USP without enzymes (From FDA Draft Guidance, Jan, 1999.)

physiological conditions. For this purpose, determination of pH-solubility profiles over a pH range of 1–8 is suggested. Preferably eight or more pH conditions should be evaluated. Buffers that react with the drug should not be used. An acid or base titration method can also be used for determining drug solubility. The solubility class is determined by calculating what volume of an aqueous media is sufficient to dissolve the highest anticipated dose strength. A drug substance is considered highly soluble when the highest dose strength is soluble in 250 ml or less of aqueous media over the pH range of 1–8. The volume estimate of 250 ml is derived from typical bioequivalence study protocols that prescribe administration of a drug product to fasting human volunteers with a glass (8 ounces) of water.

Solution stability of a test drug in selected buffers (or pH conditions) should be documented using a validated stability-indicating assay. Data collected on both pH-solubility and pH-stability should be submitted in the biowaiver application along with information on the ionization characteristics, such as pKa(s), of a drug.

Determining Permeability Class

Studies of the extent of absorption in humans, or intestinal permeability methods, can be used to determine the permeability class membership of a drug. To be classified as highly permeable, a test drug should have an extent of absorption >90% in humans. Supportive information on permeability characteristics of the drug substance should also be derived from its physical–chemical properties (e.g., octanol:water partition coefficient).

Some methods to determine the permeability of a drug from the GI tract include 1) in vivo intestinal perfusion studies in humans, 2) in vivo or in situ intestinal perfusion studies in animals, 3) in vitro permeation experiments using excised human or animal intestinal tissues, and 4) in vitro permeation experiments across a monolayer of cultured human intestinal cells. When using these methods, the experimental permeability data should correlate with the known extent-of-absorption data in humans.

Table 10 Postapproval change levels

Change level	Example	Comment
Level 1	Deletion or partial deletion of an ingredient to affect the color or flavor of the drug product	Level 1 changes are those that are unlikely to have any detectable impact on formulation quality and performance.
Level 2	Quantitative change in excipients greater than allowed in a Level 1 change.	Level 2 changes are those that could have a significant impact on formulation quality and performance
Level 3	Qualitative change in excipients	Level 3 changes are those that are likely to have a significant impact on formulation quality and performance. A Level 3 change may require in vivo bioequivalence testing.

Dissolution

The dissolution class is based on the in vitro dissolution rate of an immediate release drug product under specified test conditions and is intended to indicate rapid in vivo dissolution in relation to the average rate of gastric emptying in humans under fasting conditions. An immediate release drug product is considered rapidly dissolving when not less than 85% of the label amount of drug substance dissolves within 30 min using the USP apparatus I at 100 rpm or apparatus II at 50 rpm in a volume of 900 ml or less in each of the following media 1) acidic media such as 0.1 N HCl or Simulated Gastric Fluid USP without enzymes; 2) a pH 4.5 buffer; and 3) a pH 6.8 buffer or Simulated Intestinal Fluid USP without enzymes.

BIOWAIVERS

In addition to routine quality control tests, comparative dissolution tests have been used to waive bioequivalence requirements (biowaivers) for lower strengths of a dosage form. The drug products containing the lower dose strengths should be compositionally proportional or qualitatively the same as the higher dose strengths and have the same release mechanism. For biowaivers, a dissolution profile should be generated and evaluated using one of the methods described under Section V in this guidance, "Dissolution Profile Comparisons." Biowaivers are generally provided for multiple strengths after approval of a bioequivalence study performed on one strength, using the following criteria: For multiple strengths of IR products with linear kinetics, the bioequivalence study may be performed at the highest strength and waivers of in vivo studies may be granted on lower strengths, based on an adequate dissolution test, provided the lower strengths are proportionately similar in composition [21 CFR 320.22(d)(2)]. Similar may also be interpreted to mean that the different strengths of the products are within the scope of changes permitted under the category "Components and Composition," discussed in the SUPAC-IR guidance.

SCALE-UP AND POSTAPPROVAL CHANGES (SUPAC)

After a drug product is approved for marketing by the FDA, the manufacturer may want to make a manufacturing change. The pharmaceutical industry, academia and

the FDA developed (2, 3, 5, 3, 10, 3, 12–17) a series of guidances for the industry that discuss scale-up and postapproval changes, generally termed, SUPAC guidances (11). The FDA SUPAC guidances are for manufacturers of approved drug products who want to change 1) a component and composition of the drug product; 2) the batch size; 3) the manufacturing site; 4) the manufacturing process or equipment; and/or 5) packaging. These guidances describe various levels of postapproval changes according to whether the change is likely to impact on the quality and performance of the drug product. The level of change as classified by the FDA as to the likelihood that a change in the drug product might affect the quality of the product (Table 10).

BIODEGRADABLE POLYMERS AS DRUG CARRIERS

Peter Markland

Southern Research Institute, Birmingham, Alabama, U.S.A.

Victor C. Yang

The University of Michigan, Ann Arbor, Michigan, U.S.A.

OVERVIEW

Polymers first developed in the search for biodegradable suture materials have proven to be useful and successful for long-term drug delivery applications. Biodegradable polymers are highly desirable in these situations because they degrade in the body to biologically inert and compatible molecules. By incorporating drug into biodegradable polymers, dosage forms that release the drug over a prolonged length of time can be prepared in a variety of shapes and sizes. No secondary surgical procedures are needed after completion of the dosing regimen since the remaining polymer dosage form will be degraded and cleared by the body. As a result, biodegradable polymers offer a novel approach for developing sustained release drug delivery systems that are simple and convenient to the patient.

Many different biodegradable polymer chemistries have been proposed for these applications; however, the most common and successful are the polyesters that were first investigated as degradable sutures. These polymers include poly(glycolide), poly(D,L-lactide), and their related copolymers poly(D,L-lactide-co-glycolide). Many commercial products based on these materials are currently on the market, including Decapeptyl[®], Lupron Depot[®], and Sandostatin LAR[®]. In traditional parenteral depot applications, biodegradable polymers have been used simply as inert carrier vehicles. Preparation of the dosage form was carried out, by various means, by simply incorporating the drug into the polymer matrix. However, the effective delivery of new drug therapies, including peptides, proteins, and genetic- and cell-based drugs, places greater demands on the performance of the polymer platform. Consequently, new polymer chemistries and novel dosage form design are being investigated in attempts to produce tailor-made dosage forms that are capable of enhancing the delivery and efficacy of these drugs.

INTRODUCTION

A wide variety of delivery systems have been developed for the purpose of prolonging the release and, ultimately, bioavailability of drugs to the body. Examples include the transdermal patch, oral dosage forms such as osmotic pumps and swellable hydrophilic polymer matrices, and various types of polymer-based parenteral depot formulations (1, 2). Depot sustained release formulations can overcome limitations associated with oral or transdermal administration routes. Several of these limitations include poor drug stability in the GI tract, low drug permeability through the GI mucosa or stratum cornea, rapid clearance from first-pass metabolism, and the need for delivery for more than a few days. Many interesting and successful parenteral depot systems for sustained release applications have been developed. Such systems can be distinguished into degradable and nondegradable delivery systems based on the properties of the polymers.

One example of a nondegradable delivery system is Norplant[®] (Wyeth-Ayerst) which has been shown successful in prevention of pregnancy for up to five years (3). This delivery system consists of six small, closed tubes made of a silicone rubber copolymer of dimethylsiloxane and methylvinylsiloxane (Silastic[®]) and is implanted subcutaneously by scalpel incision or via trocar. Each tube contains 36 mg of the progestin hormone levonorgestrel. At termination of the dosing regimen, a nondegradable delivery system like this requires a secondary surgical procedure to retrieve the implanted device from the body. Such a retrieval procedure can be undesirable for several reasons including the added cost, the possibility of complications during retrieval, the risk of infection, and the lack of patient compliance. Although Norplant[®] is widely considered a safe and highly cost-effective method of contraception (4), there nevertheless has been a precipitous drop in demand for this product in

the United States since 1994. This decrease in interest has been attributed, in large part, to the difficulties associated with removal of the implanted rods along with the publicity created by these clinical problems (5).

Consequently, polymers that can degrade into biologically compatible components under physiologic conditions present a far more attractive alternative for the preparation of drug delivery systems. The use of biodegradable polymers precludes the need for retrieval at the conclusion of the dosing regimen, thereby avoiding the potential complications associated with the use of nondegradable systems. Degradation may take place by a variety of mechanisms, although it generally relies on either erosion or chemical changes to the polymer. Degradation by erosion normally takes place in devices that are prepared from soluble polymers. In such instances, the device erodes as water is absorbed into the system causing the polymer chains to hydrate, swell, disentangle, and, ultimately, dissolve away from the dosage form. Alternatively, degradation could result from chemical changes to the polymer including, for example, cleavage of covalent bonds or ionization/protonation either along the polymer backbone or on pendant side-chains. A number of degradation schemes have been described that characterize how chemical degradation of the polymer or of polymer-drug conjugates can be utilized to achieve drug release (6, 7).

The most widely studied biodegradable polymers include those which undergo chemical degradation through random hydrolysis of the covalent bonds constituting the backbone of the polymer chains. Random chain scission results in a reduction in the molecular weight of the polymer. As this process continues over time, polymer chains become progressively shorter resulting, at some point in time, in the loss of mechanical integrity in the dosage form. Ultimately, the degradation process proceeds until polymer fragments are degraded to soluble oligomers or individual monomers. As a necessity due to this process, biodegradable polymers and their degradation products must be biologically compatible and nontoxic. Consequently, the monomers typically used in the preparation of biodegradable polymers are often molecules that are endogenous to biological systems. The most common class of biodegradable polymers is the hydrolytically labile polyesters prepared from lactic acid, glycolic acid, or combinations of these two molecules. Polymers prepared from these individual monomers include poly(D,L-lactide) (PLA), poly(glycolide) (PGA), and the copolymer poly(D,L-lactide-co-glycolide) (PLG).

The distinctions between chemical and erosion degradation mechanisms, however, are by no means

absolute, and there are instances where both processes contribute to the overall degradation and resorption of a drug delivery system. For instance, copolymers of glutamic acid and ethyl glutamic acid have been studied for the release of the narcotic antagonist naltrexone (8). In this case, hydrolysis of the ethyl ester side-chain converts this copolymer to the soluble polymer poly(glutamic acid). Following hydrolysis, the polymer device erodes as the soluble polymer chains dissolve away from the device. In addition, there are many other examples where both chemical degradation and physical erosion are involved in the final disintegration and resorption of the dosage form. In this regard, the terms such as "biodegradable" and "bioerodible" are sometimes used interchangeably in the literature while, at other times, they can be used to refer to distinct degradation processes. Consequently, care should be taken when reviewing the literature to interpret how these terms are being used. In some cases, the term "biodegradation" is limited to the description of chemical processes (chemical changes that alter either the molecular weight or solubility of the polymer) while "bioerosion" may be restricted to refer to physical processes that result in weight loss of a polymer device.

HISTORY

The use of biodegradable polymers in drug delivery applications grew from the search for polymers that could be employed as degradable sutures. Synthetic polymers such as poly(glycolic acid) were first developed in the 1950s (9); however, their poor hydrolytic stability made them unsuitable for permanent applications. This attribute, however, made these materials useful for applications such as sutures that could benefit from their ability to degrade in the presence of moisture (10, 11). Examples include Dexon[®] and Vicryl[®] sutures prepared from poly(glycolic acid) and poly(lactide-co-glycolide), respectively (10, 12). The utility of these materials as degradable sutures further led to their application in the development of sustained release drug delivery formulations. In 1970, Yolles et al. reported the use of the poly(lactic acid) biodegradable system for delivery of the narcotic antagonist cyclazocine (13). At about the same time, a number of other drugs including anticancer agents (14), steroids (15), and other narcotic antagonists (16–18) were reported to be delivered from biodegradable formulations. Many reviews catalog the early development of this technology for the sustained delivery of a variety of small molecule drugs (19–21).

More recently, the growth of biotechnology has led to the identification of many potent and powerful protein- and

gene-based macromolecular drugs. However, delivery of these drugs to the body in an efficacious manner without sacrificing the quality of life of the patient continues to be a major obstacle. Gastric proteases and low permeability across the gastrointestinal epithelium mean that macromolecular drugs have poor bioavailability via the oral route. Instead, these drugs are normally dosed by injection (e.g., subcutaneous, intramuscular, or intravenous). However, the short biological half-lives of these molecules requires that frequent parenteral injections be performed in order to maintain treatment efficacy. Despite the obvious need to develop long-term delivery systems for these highly valuable drugs, the application of this technology has been fraught with obstacles (22–24). Polymer–drug interactions, processing conditions, and the internal pH, temperature, and moisture levels within the implanted device have contributed to difficulties retaining drug stability before being released from the implanted device.

In spite of these complications, considerable achievements have been made in the development of biodegradable delivery systems for proteins and, in particular, bioactive peptides. Most of the commercial success over the past decade has been achieved using the polyester PLA and the various copolymers of PLG. In particular, a number of biodegradable delivery systems have been developed for synthetic analogs of luteinizing hormone-releasing hormone (LHRH). Sanders et al., for instance, demonstrated the release of nafarelin acetate for over 30 days from microsphere formulations of PLG with a

50:50 molar ratio of the lactide and glycolide monomers (50:50 PLG) (25). The first such system to the market was Decapeptyl® (Ipsen Biotech), a microsphere depot formulation for treatment of prostate cancer (Fig. 1) (26). This product delivers 3.75 mg of an LHRH analog over a 30-day period. More recently, TAP Pharmaceuticals (Deerfield, IL) commercialized a series of depot microsphere formulations of the LHRH analog leuprolide acetate under the trade name Lupron Depot®. Products prepared from either PLG or PLA are presently available that can provide peptide release over 1, 3, and 4 months (3). Lupron Depot® formulations are indicated for the treatment of endometriosis (27), prostate cancer (28), and precocious puberty in children (29).

In contrast to these microsphere formulations, Zoladex® (AstraZeneca) is a small implantable cylinder (approximately 1 mm in diameter and 10 mm in length) containing goserelin acetate in a polymer matrix of 50:50 PLG. This system delivers approximately 3.6 mg drug over a 1-month period and is indicated for the treatment of prostate cancer. A second Zoladex® system containing 10.6 mg goserelin has also been developed to release the drug for over 3 months (3).

The synthetic somatotropin analog octreotide acetate has been successfully formulated into a microsphere formulation composed of PLG. This product, Sandostatin LAR® (Novartis), has been used for acromegaly treatment (30) as well as the treatment of diarrhea and flushing episodes associated with metastatic carcinoid (31).

Fig. 1 Serum LH and testosterone concentrations of 22 human subjects treated at 5 week intervals with the biodegradable depot formulation Decapeptyl (3 mg LHRH per dose). (From Ref. 26.)

Fig. 2 The influence of Sandostatin LAR biodegradable depot formulation on the mean plasma growth hormone concentrations in humans. Plasma concentrations are shown over a 24 hour period 28 days after administration of a second monthly 20 mg dose of Sandostatin LAR, ●. For comparison, plasma concentrations are provided for untreated controls, ■, and for patients receiving multiple daily subcutaneous octreotide injections, △. (From Ref. 30.)

The depot formulation, given once monthly, is reported to be as well tolerated and effective as octreotide solutions that require long-term subcutaneous dosing 2–3 times daily (Fig. 2). This example clearly illustrates the potential for biodegradable sustained release formulations to significantly improve quality of life.

In December 1999, the first protein biodegradable depot formulation received regulatory approval. Nutropin-Depot® (Genentech) contains somatotropin, a recombi-

Fig. 3 Serum human growth hormone (hGH) levels in immunosuppressed rats receiving three monthly doses of a biodegradable depot formulation containing 7.5 mg rhGH. (From Ref. 32.)

nant human growth hormone (rhGH) having a molecular weight of 22,125 D, within PLG microspheres. Protein activity was preserved by preparing the microspheres from an insoluble zinc–hormone complex (Fig. 3) (32).

While many different polymer chemistries have been developed for drug delivery applications, only one class of polymer beside the polyesters has received regulatory approval. Gliadel® is a thin wafer containing the chemotherapeutic agent carmustine (BCNU) in a poly-anhydride polymer matrix. Gliadel® received conditional approval in 1996 as an adjunct therapy following surgical removal of recurrent glioblastoma multiforme (GBM) tumors (3).

Obviously, the regulatory status of polyesters means that these materials dominate the field as far as commercial development is concerned. However, there is a myriad assortment of polymers that continue to be developed for drug delivery applications. These efforts are aimed at developing new polymeric materials designed specifically to overcome obstacles in drug delivery, bioavailability, or stability. Additionally, new engineering or processing techniques are also being developed to aid the design of novel dosage forms that can enhance drug delivery characteristics and the use of these polymeric materials in a variety of new biomedical applications.

FACTORS AFFECTING POLYMER SELECTION

Both synthetic polymers and those derived from naturally occurring sources have been evaluated in biodegradable drug delivery applications. Examples of several classes of biodegradable polymers are presented in Table 1. There are a variety of polymer properties or attributes to be considered when selecting a biodegradable polymer. Many of these are listed in Table 2. One of the most critical considerations is the regulatory requirement for a particular application. If an application requires rapid development and commercialization, then the polymer selection will most likely be made from among those polyesters that have already received regulatory approval. Another factor to consider is whether to use homopolymers consisting of a single monomeric repeat unit or copolymers containing multiple monomer species. If copolymers are to be employed, then the relative ratio of the different monomers may be manipulated to change polymer properties. It should be noted that polymer composition would directly dictate many of the polymer physicochemical properties listed in Table 2 including bulk hydrophilicity, morphology, structure, and the extent of drug–polymer interactions (e.g., drug solubility in the

Table 1 Common classes and examples of biodegradable polymers

Type	Class	Examples
Synthetic polymers	Polyamide	Polyamino acids, Polypeptides
	Polyester	Poly(glycolide)
		Poly(D,L-lactide)

		Collagen
		Gelatin
		Bovine serum albumin (BSA)
		Human serum albumin (HSA)

polymer). Ultimately, these properties will all influence the performance of the drug delivery system via changes to the relative rates of mass transport (e.g., water in and solute or drug out of the system) and the degradation rate of both the polymer and the device.

In addition to polymer composition, the thermal attributes of the polymer, as described by the glass transition temperature (T_g) and melting temperature (T_m), can also affect the mass transport rates through the polymer as well as the polymer processing characteristics and the stability of the dosage form. Below the glass transition temperature, the polymer will exist in an amorphous, glassy state. When exposed to temperatures above T_g , the polymer will experience an increase in free volume that permits greater local segmental chain mobility along the polymer backbone. Consequently, mass transport through the polymer is faster at temperatures above T_g . Often, polymer processing, such as extrusion or high-shear mixing, is performed above T_g . On the other hand, the greatest stability during storage of a polymer device may be obtained at temperatures below T_g , where solute diffusion is much slower and more subtle changes in polymer properties (e.g., tackiness) are reduced.

The presence of plasticizers, such as residual solvent or dissolved solutes including the drug or other additives, will tend to lower polymer T_g . Conversely, features that hinder segmental motion along the polymer, such as greater chain rigidity, bulky side groups, and ring structures, would tend to increase T_g . Finally, the presence of charged groups on a polymer can also influence drug release from the device. The number and density of ionized groups along the polymer backbone, on the side-chain groups, or at the terminal end-groups of the polymer chains can all vary the extent of polymer–polymer and polymer–drug interactions. In this manner, ionizable groups can affect drug solubility in the polymer and, correspondingly, the release rate from the polymer. A number of reviews which describe in detail of the relationship between polymer properties and performance in drug delivery applications have been published (33, 34).

FACTORS AFFECTING DRUG RELEASE

Aside from the physicochemical properties of the polymer itself, there are additional factors that can influence drug

Table 2 Properties affecting polymer selection, manufacture, and performance

Property	Examples
Regulatory and toxicology status	
Monomer or copolymer composition	
Molecular weight	M_w , M_n
Molecular weight distribution	Polydispersity ratio (M_w/M_n)

Morphology	Amorphous Semicrystalline Crystalline
Thermal transition temperatures	Melting temperature, T_m Glass transition temperature, T_g
Ionization	Side-chains Main-chain end groups

release and the performance characteristics of the dosage form. Examples of these factors are highlighted in Table 3. Dosage forms can be formulated into a wide range of geometries and physical forms and sizes. The appropriate selection would depend on the flexibility with which a polymer can be processed, the desired route of administration, the duration of action, and the stability

of the drug under processing conditions. Additionally, the drug distribution in the dosage form can be either homogeneous (a monolithic or matrix system) or heterogeneous (reservoir system). Finally, the rate and mechanism by which the polymer degrades can also influence drug release and, potentially, drug stability following administration. If necessary, systems can be designed so that release of the drug load is completed before polymer degradation begins to affect the integrity of the dosage form. Conversely, a dosage form can also be designed in a way that polymer degradation and device erosion can both contribute to drug release.

Based on the above reasons, polymers possessing a variety of degradation rates and mechanisms have been developed; however, hydrolysis still remains the predominant degradation mechanism for polymers that are most commonly used in drug delivery applications. Many polymers that are susceptible to hydrolysis, for example, the polyesters PLA and PLG, degrade by random hydrolysis that takes place homogeneously throughout the bulk of the polymer device. In contrast, other classes of polymers, such as the polyanhydrides and polyorthoesters, have been developed in an attempt to yield hydrolysis only at the outer surface of the device that is exposed directly to the aqueous environment. When this so-called surface-erosion process is achieved, hydrolysis is believed to take place in a heterogeneous manner, and the polymer device degrades from the outside toward the center.

Reservoir systems are designed to have the drug deposited inside of a polymer membrane. In such systems where the polymer membrane serves as the barrier, drug release is controlled by Fickian diffusion of the drug

Table 3 Device attributes affecting performance

Property	Attribute	Examples
Design of delivery device	Shape/geometry	Cylinder or rod
		Microparticles (microsphere, microcapsule, nanoparticle)
	Drug distribution	Film or sheet
		Viscous gel or liquid

		Porosity
	Mechanism	Homogeneous degradation (bulk)
		Heterogeneous degradation (surface-erosion)

through the membrane, and the release rate can be described by the following relationship:

$$\frac{dM_t}{dt} = \frac{ADC_s}{t_m} \quad (1)$$

where M_t is the mass of drug released at time t , A is the surface area of the barrier membrane, D is the diffusion coefficient of the drug in the membrane, C_s is the solubility of the solute in the polymer, and t_m is the membrane thickness (35). As long as the drug concentration in the reservoir remains well above saturation and the membrane thickness is small relative to the other dimensions of the device, this relationship indicates that the drug release rate should be constant over time (zero-order) so long as release was diffusion controlled. Because biodegradable polymers are chemically unstable, they are generally not used to prepare reservoir delivery systems. The potential for these polymers to degrade prematurely thereby releasing the remaining contents of the drug reservoir presents a safety concern.

More typically, therefore, biodegradable polymers are used to prepare matrix (monolithic) systems in which the drug is dispersed or dissolved homogeneously throughout the polymer. Matrix systems can be prepared in a multitude of forms including films, sheets, cylinders, rods, and microparticles (e.g., microspheres and nanospheres). Drug is initially released from the exposed, outer surfaces of this type of dosage form. As these regions become depleted of drug, release continues as drug is transported from increasingly deeper regions of the dosage form. Because the diffusional path length gets continuously longer during the release process, diffusion-controlled release from matrix systems is not zero-order. Based on a thin-slab geometry, Higuchi derived a relationship which, when differentiated, yields the following prediction for the diffusion-controlled release rate from a matrix system (35):

$$\frac{dM_t}{dt} = \frac{A}{2} \left(\frac{DS_s(2C_L - C_s)}{t} \right)^{\frac{1}{2}} \quad (2)$$

where A is the area of the polymer slab, C_L is the drug loading in the device and the remaining variables are the same as defined in Eq. (1). This relationship suggests that when diffusion-controlled release is achieved, the drug release rate will decrease proportionately with $t^{-1/2}$, assuming that polymer degradation does not contribute to drug release.

Results obtained by quantitatively monitoring drug release from monolithic matrix systems indicate that low-molecular-weight drugs can be released at rates that are consistent with a diffusion-controlled mechanism. High-

molecular-weight drugs such as peptides and proteins, however, generally have little permeability through the polymer phase due to their low polymer solubility and diffusion rates. Consequently, these molecules are unlikely to be released from monolithic systems by purely diffusion-controlled mechanisms. Instead, release of peptides and proteins from polymer matrices needs to be aided by additional mechanisms that can facilitate mass transport out of the device (36). For example, release can be enhanced by the formation of pores or channels that are created by the continuous dissolution and removal of soluble components, such as the drug or other formulation excipients, from the polymer matrix. Alternatively, drug release can also be enhanced by polymer degradation and the subsequent erosion of the device itself. A variety of mathematical models have been proposed to correlate the effects of both polymer degradation and drug diffusion on the overall release rate (20, 37, 38).

In a special case, novel systems have been developed that are capable of providing zero-order drug release profiles. Surface-eroding polymers in which polymer degradation takes place only at the outer surfaces of the device have been prepared. When drug release can be limited to regions undergoing degradation, a constant drug release profile is possible. In this case, the polymer degradation rate can be used to control the release rate of the drug. Hopfenberg developed a mathematical model to correlate this type of drug release system so long as the surface area remains constant during the degradation process (39). The cumulative fraction of drug released at time t was described by:

$$\frac{M_t}{M_\infty} = 1 - \left(1 - \frac{k_0 t}{C_L a} \right)^n \quad (3)$$

where k_0 is the zero-order rate constant describing the polymer degradation (surface-erosion) process, C_L is the initial drug loading throughout the system, a is the system half-thickness (i.e., the radius for a sphere or cylinder), and n is an exponent that varies with geometry [$n = 1, 2$, and 3 for slab (flat), cylindrical, and spherical geometry, respectively] (39).

COMMON CLASSES OF BIODEGRADABLE POLYMERS

Polyesters

A variety of hydrolytically labile polyesters have been evaluated in drug delivery applications. Several

examples are listed in Table 4. Among these, however, poly(glycolide), poly(lactide), and various copolymers of poly(lactide-co-glycolide) are the ubiquitous choice because of their proven safety and lack of toxicity, their wide range of physicochemical properties, and their flexibility to be processed into a variety of physical dosage forms. These polymers and copolymers are prepared by anionic ring-opening reaction of highly purified glycolide and lactide monomers, the cyclic dimers of glycolic acid and lactic acid, respectively. Stannous octoate (tin(II) 2-ethyl hexanoate) is the chain initiator most commonly used in the synthesis of polymers for pharmaceutical applications. Because the lactide monomer possesses two chiral carbons, polymerization may be performed using D-lactide (the D-,D-cyclic dimer), L-lactide (the L-,L- cyclic dimer), or the meso-lactide (the D-,L- cyclic dimer). Synthesis of poly(D,L-lactide) (PLA), though, is most commonly performed by copolymerization of a racemic mixture of the D- and L-lactide monomers. In a similar manner, the copolymer poly(D,L-lactide-co-glycolide) (PLG) is generally prepared using varying ratios of the glycolide to a racemic blend of D-/L-lactides. Because PLA and PLG are prepared from distinct monomer species, there exists the possibility that polymerization may result in a nonrandom sequence of monomer species (21). Compositional heterogeneity can lead to variability in properties between polymer lots. Historically, this has been problematic for PLG polymers containing 50% glycolide (50:50 PLG).

Homopolymers of poly(D-lactide) and poly(L-lactide) tend to be semi-crystalline. As a result, water transport into these polymers is slow. Because of the slow uptake of water and the structural integrity introduced by crystallites, degradation rates of these polymers tend to be relatively slow (i.e., 18–24 months) (21). In contrast, poly(D,L-lactide) (PLA) is amorphous and is observed to degrade somewhat faster (i.e., 12–16 months). Adding increasing proportions of glycolide into PLA lowers T_g and generally increases polymer hydrophilicity. These PLG copolymers generally remain amorphous as long as the glycolide content remains within the range of about 0–70 mole%. In contrast, poly(L-lactide-co-glycolide) is amorphous when the glycolide content is 25–70 mole%. The most rapid degradation rate (i.e., 2 months) is observed in PLG copolymers containing 50% glycolide. Poly(glycolide), despite being semi-crystalline, is found to degrade relatively fast (i.e., 2–4 months) even compared to the amorphous PLA. This is attributed to the much greater hydrophilicity of the glycolide over the lactide. Actual degradation times, though, will depend on environmental conditions, polymer molecular weight,

system geometry and morphology, and processing conditions (21, 40, 41).

After exposure to and equilibration in an aqueous environment, polyesters degrade by hydrolysis that occurs homogeneously throughout the bulk of the polymer device. Evidence commonly used to support such a conclusion is that the bulk degradation of the polymer device (as indicated by weight loss) lags behind the decrease in polymer molecular weight over time (Fig. 4). However, other studies have provided evidence of nonhomogeneous hydrolytic degradation under certain circumstances. Devices prepared from amorphous polyesters including PLA and 75:25 PLG have been reported to exhibit accelerated degradation within the interior of the device (42). This phenomenon has been attributed to acid-catalyzed polymer hydrolysis resulting from the build-up in these regions of acidic oligomers and monomers during the degradation process. In these instances, the devices are either large in physical dimensions or they are nonporous, meaning that the acidic by-products cannot be readily washed away from the interior of the device. Alternatively, heterogeneous degradation in semi-crystalline polymers such as poly(glycolide) results from the preferential diffusion of water into the amorphous regions. As a result, degradation occurs in the amorphous regions leaving behind crystalline-rich portions that hydrolyze more slowly (43, 44). Initially amorphous polymers such as PLA and 75:25 PLG have also been found to exhibit heterogeneous degradation, reportedly through the crystallization of polymer fragments rich in L-lactide during the course of hydrolysis (43).

Fig. 4 Degradation profiles of cylindrical PLG rods incubated at 37°C in vitro. Degradation is exhibited by the percent change over time of the sample weight, ■, and number-average molecular weight (M_n), □. (Adapted from Ref. 25.)

Many reviews describing the development of polyester-based biodegradable drug delivery systems have been published (21, 22, 40, 22, 45). Much work has been performed in evaluating these materials for delivery of proteins (36) and vaccines (46). More recently, novel chemical and engineering approaches have been discovered to make crosslinked hydrogels and three-dimensional porous matrices for a wide range of biomedical applications including, protein and gene delivery as well as cell therapy.

Polyanhydrides

Historically, polyanhydrides were developed in the textile industry during the first half of the 20th century as alternate fiber materials (47, 48). However, the modern polyanhydrides that are currently under investigation as drug delivery platforms represent a novel class of polymer that, unlike the polyesters, has been specifically developed for biodegradable applications. In particular, these polyanhydrides were specifically prepared in attempts to produce surface-eroding dosage forms.

The anhydride linkages of these polymers are, in general, more hydrolytically labile than the polyester bond. In order to achieve a surface-eroding mechanism, polymers are generally prepared from very hydrophobic monomers in order to minimize water penetration into the bulk of the device. By doing this, hydrolysis of the labile anhydride linkages would be restricted to the outer exposed surfaces of the polymer device. A wide variety of aliphatic and aromatic monomers have been used to prepare surface-eroding polyanhydride polymers (Table 5). Aliphatic polyanhydrides are normally prepared from dicarboxylic acids such as adipic acid, sebacic acid (SA), dodecanoic acid, and fumaric acid (FA). Additionally, diacidic fatty acid monomers (fatty acid dimers, or FAD) have also been used. Polymers with increasing hydrophobicity can be made from aromatic monomers including phthalic acid and various carboxyphenoxyalkanes such as CPM, CPP, and CPH (Table 5). High-molecular-weight polyanhydrides are usually synthesized by first converting the dicarboxylic acid monomer to mixed anhydride prepolymers using acetic anhydride followed by polymerization of prepolymers using polycondensation reaction in the melt.

Typically, homopolymers are not studied because they possess unfavorable characteristics rendering their handling and manufacture difficult. Poly(SA), poly(CPP), and poly(FA) are semicrystalline and thus suffer from either being brittle or having high T_m . Conversely, poly(FAD) is a liquid. Therefore, polyanhydrides are often prepared as copolymers of aliphatic and/or aromatic monomers. The

most common copolymers under investigation in drug delivery applications include poly(FAD-SA) and poly(CPP-SA).

Studies on aliphatic polyanhydrides have shown that increasing the alkyl chain length (e.g., from $n = 4$ to 12) of the dicarboxylic acid monomers increases polymer hydrophobicity resulting in a decrease in both polymer degradation and drug release rates (49). These trends in degradation were observed both in vitro and in vivo. While poly(FAD) is amorphous, the degree of crystallinity observed in poly(FAD-SA) copolymers increased directly once the SA content was raised above 30 mole%. In spite of this, raising the SA content has been shown to increase the degradation rate. This can be attributed to the greater hydrophilicity of SA relative to FAD (50). In contrast, poly(CPP-SA) copolymers are semicrystalline across the entire range of composition, yielding the lowest degree of crystallinity when the SA content is between 15 and 70 mole%. While having little influence on polymer crystallinity, changes in copolymer composition can affect polymer degradation rates. Figure 5 shows the relative in vitro degradation rates of poly(CPP-SA) copolymers containing 0–79 mole% SA. In these samples, degradation of 100% poly(CPP) was estimated (by extrapolation) to require over 3 years, whereas copolymers containing the highest amounts of SA degraded as quickly as 1–2 weeks. The initial motivation for synthesizing polyanhydrides was to prepare devices that degrade at a constant rate by a surface-erosion process. To this end, nearly zero-order degradation profiles were achieved for over a 6-day period for discs prepared from poly(SA) and also from poly(CPP-SA) containing 80 and 20% SA. Similarly, poly(CPP) and 85:15 poly(CPP-SA) also showed constant degradation profiles that lasted for a period of several months.

Degradation of poly(FAD-SA) has also been reported to be nearly zero-order based on the rate of SA release from the polymer (50). However, evidence suggests that devices prepared from these polymers do not necessarily degrade by a purely surface-erosion mechanism. Cumulative release profiles of individual monomers released from a degrading poly(CPP-SA) matrix indicated that SA was released at a much faster rate than was CPP. Other studies have shown that, similar to certain polyesters, amorphous regions in poly(CPP-SA) will preferentially hydrolyze first, leaving behind a network of pores surrounding the remaining crystalline-rich structures (48). These findings suggest that while polyanhydrides are able to provide degradation behavior that is consistent with a surface-erosion mechanism, the actual processes involved in polymer degradation and erosion of the device can be more complicated.

The release of a number of drugs from polyanhydride matrices has been studied including ciprofloxacin (49), *p*-nitroaniline (47, 51), cortisone acetate (51), insulin (51), and a variety of proteins (50). In many instances, drug release was reported to coincide with polymer degradation. The biocompatibility of polyanhydrides has also been assessed in a number of studies (51–54). The only commercial product that has received regulatory approval is Gliadel[®]. This product is a thin wafer (1.45 cm in diameter, 1 mm in thickness) containing 7.7 mg carmustine(BCNU), and is prepared from 20:80 poly(CPP-SA). As many as 8 wafers are implanted in the cavity created after surgical removal of recurrent glioblastoma multiforme, an aggressive form of brain cancer. Studies show that BCNU release from Gliadel[®] wafers is controlled by both drug diffusion and erosion of the polyanhydride matrix (55).

Polyorthoesters

A series of polyorthoesters has been under development since 1970 in efforts to prepare surface-eroding biodegradable polymers specifically for drug delivery applications (56–61). The first hydrolytically labile polyorthoesters were synthesized by polycondensation of a diol (either 1,6-hexanediol, HD, or *cis/trans*-1,4-cyclohexane dimethanol, CHDM) with an orthoester (diethoxy tetrahydrofuran, DETHF). This polymer was initially called Chronomer[™] and was developed at the Alza Corporation (Palo Alto, CA) by Choi and Heller (Table 6). Later the name was changed to Alzamer[®];

development of these polymers has since been discontinued. Hydrolysis of Alzamer[®] produces the corresponding diol along with γ -hydroxybutyrolactone which rapidly opens its ring structure to form γ -hydroxybutyric acid. Because polymer hydrolysis was acid catalyzed, production of this by-product accelerated the rate of degradation of the remaining polymer. In order to avoid catastrophic self-accelerated hydrolysis, the polymer was usually stabilized by the addition of an inorganic base such as sodium carbonate.

In attempts to overcome the limitations of these polymers, Heller developed alternate polyorthoesters at SRI International (Palo Alto, CA). The second generation polyorthoesters were prepared by the addition of a diol with the cyclic diketene acetal, 3,9-diethylidene-2,4,8,10-tetraoxaspiro [5.5] undecane (DETOU) (Table 5). When prepared with varying ratios of these two diols (i.e., HD and CHDM), polyorthoesters possessing a wide range of mechanical properties could be obtained. Increasing the HD composition from 0 to 100% lowered the polymer T_g from over 100°C to about 20°C accordingly (57). In addition, the T_g of DETOU polyorthoesters can be further reduced by synthesis using linear diols of successively longer alkyl chain length. Increasing the alkyl length from $n = 6$ to $n = 12$ lowers T_g from 20 to 0°C (59). The reduction in glass transition temperatures of these polymers reflects the increased chain flexibility of the diol component.

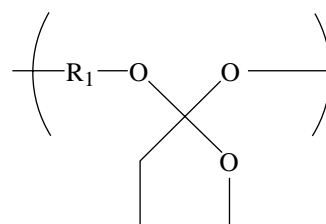

DETOU polyorthoesters, because of the hydrophobic nature of the monomers are found to degrade relatively slowly in vitro with only 15% weight loss after about 150 days and 60% weight loss after 325 days. These polymers are also shown to hydrate slowly (i.e., adsorbing about 0.3–0.75 wt% of water). While degradation of the DETOU polyorthoester is also acid-catalyzed, the degradation products do not generate any acidic species. Heller suggested that a faster polymer degradation could be achieved by the addition of acidic excipients into the polymer matrix. When 1 wt% suberic acid was added to a DETOU polyorthoester polymer prepared with 1,6-hexanediol, a complete release of naltrexone pamoate was achieved in vitro in 30 days (57). Conversely, the polymer can be stabilized against hydrolysis by the addition of a base such as magnesium hydroxide.

One potential limitation to the use of blended excipients to regulate polymer degradation rates is the likelihood that the excipient could diffuse out of the device before polymer degradation has terminated. For acidic additives, this would cause polymer erosion to slow down significantly, meaning that polymer residues would remain in the implanted tissue site for a long time. To avoid this possibility, novel approaches have been developed to

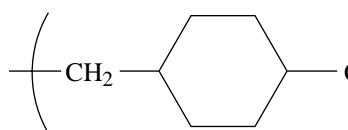

Polyorthoester linkage

$$\left(\text{R}_1 - \text{O} - \underset{\begin{array}{c} | \\ \text{O}-\text{R}_2 \\ | \end{array}}{\text{CH}} - \text{O} \right)_n$$

Polyorthoester I, with:

$\text{R}_1 = \textit{cis/trans}$ -cyclohexyl dimethanol, CHDM:

$\text{R}_1 = 1,6\text{-hexanediol}, \text{HD}: \quad \left(\text{CH}_2 \right)_6$

retain acidic species within the polymer. For example, hydrolytically labile ester bonds have been incorporated into the polymer network. Degradation of these groups produced acidic species that remained covalently attached to that polymer system over time.

Reaction of a triol such as 1,2,6-hexanetriol with a DETOU prepolymer permits the formation of a crosslinked network. Rod-shape polymer systems (2.4 mm in diameter) were fabricated containing 30 wt% levonorgestrel and 7 wt% micronized $\text{Mg}(\text{OH})_2$ as a stabilizer. These devices contained 1 wt% 9,10-dihydroxystearic acid to modify polymer erosion rate. SEM photomicrographs of the rods show evidence of surface erosion following implantation for up to 16 weeks. A degradation zone is observed to move progressively toward the center of the rod while, at the same time, erosion causes this region to become increasingly more porous as the polymer continues to degrade (56).

Heller and colleagues at Advanced Polymer Systems (Redwood City, CA) continue to develop additional polyorthoesters with a variety of physical properties and potential applications (60,61). Generally speaking, polyorthoesters do possess the potential to exhibit surface-eroding behavior. However, several issues that may limit the commercial application of this class of polymers are still present. One issue is that synthesis of these polymers involves complicated monomers and polymerization chemistry. The second issue is, to date, the toxicology and biocompatibility of these polymers and their degradation products have not yet been fully characterized. Finally, the requirement for pH-regulating additives such as acids and bases can be undesirable in applications where the drug stability is affected.

Phosphorus-Containing Polymers

There are two common classes of phosphorus-containing polymers, the phosphazenes (Table 7) and phosphoesters (Table 8). In both cases, polymers possessing a range of chemical, physical, and mechanical properties can be synthesized through simple changes in monomer side-chain substitution. Polyphosphazenes contain alternating phosphorus-nitrogen double and single bonds and are synthesized by reaction of poly(dichlorophosphazene) with organic nucleophiles such as alkoxides, aryloxides, or amines (62, 63). Polymer prodrugs have been prepared in which the drug entity is covalently attached to the polyphosphazene. Examples of these systems include the drugs procaine, benzocaine, and heparin. More typically, however, side-chain substituents are selected in order to vary polymer hydrophobicity as well as the hydrolytic stability of the phosphazene bond. Copolymers containing

varying ratios of imidazole and methylphenoxy side-chains have been prepared (Table 7) (62). Increasing the imidazole content of these polymers increases the reactivity toward hydrolysis of the phosphazene linkages. After 600 hours in phosphate buffer, a polyphosphazene containing 20% imidazole lost only 4% weight due to degradation, whereas another polymer containing 45% imidazole lost over 30% weight. The suitability of these polymers as drug delivery platforms was evaluated using *p*-nitroaniline, progesterone, and bovine serum albumin as model drugs (62).

Polyphosphazenes have also been prepared using modified amino acid ester side-chain substituents (63) (Table 7). Studies show that the polymer containing the smallest hydrophobic side-chain constituent, glycine ethyl ester, exhibited the most rapid degradation. This was attributed to the lower steric hindrance that the small side-chain group could provide in protecting the phosphazene bond from hydrolytic attack. Cast films of this polymer were degraded in vitro by 40% (as determined by percent mass loss) after 1200 hours (50 days), whereas polymers containing longer amino acid side-chain constituents such as alanine ethyl and benzylalanine ethyl esters lost only 10–15% weight during the same time interval. Substitution at the α -carbon of the amino acid side-chain, therefore, seemed to provide a greater influence on the rate of polymer hydrolysis than the overall hydrophobicity of the ester substituent. Characterization of polymer degradation products indicated that these polymers degraded to phosphates, glycine or alanine, ethanol or benzyl alcohol, and ammonia. Drug release, as was demonstrated using ethacrynic acid and the azo dye Biebrich Scarlet, followed the same trends as did polymer degradation whereby the fastest release rates were exhibited by the glycine ethyl ester polymer. Polyphosphazenes have been studied for the delivery of proteins (64), naproxen (65,66) and colchicine (67), as well as in periodontal treatments (68).

The class of phosphoester-based polymers includes polyphosphates, polyphosphonates, and polyphosphites (Table 8). A series of phosphoesters based on bisphenol A (BPA) have been prepared and evaluated in drug delivery applications (69, 70). Polymerization was carried out by interfacial polycondensation reaction of the diol (BPA) with a phosphodichloridate. Selection of either an alkyl- or alkoxide-substituted dichloridate resulted in the synthesis of either the phosphonate or phosphate polymer, respectively. High-molecular-weight polymers (M_w between 20–40 kDa) with T_g of 103–115°C were synthesized. The uptake of water and swelling of these polymers, both in vitro and in vivo, increased with the increasing relative

hydrophilicity of the phosphate substituent. The aliphatic polyphosphate BPA-EOP exhibited the greatest water uptake and swelling during degradation, whereas the aromatic polyphosphonate BPA-PP exhibited the least. Degradation rates increased with polymer hydrophilicity. For example, the percentage weight loss in BPA-EOP and BPA-PP samples was 35 and 10%, respectively, following implantation in rabbits for 30 weeks.

Other diols have been used to prepare polyphosphoesters including 1,4-bis(hydroxyethyl)-terephthalate (BHET) and *trans*-cyclohexane dimethanol (T-CHDM). The synthesis and characterization of various polyphosphoesters have recently been reviewed (71). Of particular interest is a polyphosphoester prepared by polycondensation of an oligomeric polyester diol with ethylphosphodichloridate (EOP). In this case, the diol pre-polymer was synthesized using ethylene glycol or 1,2-propylene glycol to initiate the ring-opening condensation reaction of a cyclic lactide. This polymerization was carried out in order to prepare a low-molecular-weight oligomeric polyester diol that was then polymerized with EOP. The product, actually a poly(lactide-co-phosphate), exhibited faster degradation as the phosphate content increased. This polymer is currently being investigated by Guilford Pharmaceuticals (Baltimore, MD) for delivery of the chemotherapeutic agent paclitaxel (72).

NEW DIRECTIONS

A wide variety of approaches are continuously being pursued in the quest for improved biodegradable drug delivery systems. New and modified polymer chemistries that offer distinctive degradation and drug delivery attributes are being identified and evaluated. At the same time, innovative engineering and manufacturing methods are under development to fabricate devices and physical platforms having novel three-dimensional structural attributes. In certain instances, these products make it possible to treat entirely new therapeutic applications using biodegradable devices. One approach is through the preparation of biodegradable crosslinked polymer networks. When crosslinking is carried out using hydrophilic polymers, hydrogels that absorb a significant amount of water (for example, greater than 10 wt%) can be produced. Crosslinking can generally be achieved via three different means: by formation of covalent bonds, by ionic interactions, and by formation of highly entangled chain networks. Degradation of crosslinked polymer networks can take place by either breaking the crosslinks or the polymer backbone bonds, or by slow disentanglement and

dissolution of the polymer network. The highly swollen, three-dimensional structure of hydrogels has been an attractive feature to researchers in developing delivery systems for macromolecular drugs. A number of polymers derived from naturally-occurring constituents including alginate (73), dextran (74), collagen (75), gelatin (76), and albumin (77) have been employed to prepare hydrogels. Alternatively, proven biocompatible polymers such as PLA and PLG (78) and poly(γ -benzyl-L-glutamic acid) (79) have also been used to prepare crosslinked, synthetic hydrogels. In addition, a variety of biodegradable hydrogels based on other types of constituents have also been synthesized (80).

New approaches have been taken to design and engineer novel biodegradable drug delivery platforms. Highly porous polymer platforms with controlled pore density and size have recently been synthesized by the formation of either sponge-like or entangled fibrous matrices (81, 82). These systems are currently being investigated as extracellular matrices for cell therapy. Matrices loaded with viable cells capable of releasing bioactive agents are being investigated as implantable artificial organs. In certain studies, hepatocytes incorporated into PLA matrices were shown to remain viable for 14 days. In other studies, transplanted hepatocytes were shown to be capable of forming new liver-like tissue (83). Another example is the artificial pancreas in which the islet cells were incorporated into fibrous PGA matrices for the glucose-responsive release of insulin (84). Other polymers, such as polyphosphazene, have also been investigated for cell therapy (85), while alginate hydrogels have been explored for islet transplantation (86). The implantation of biodegradable polymer platforms seeded with osteoblast cells (87) or incorporated with bone-derived growth factors (88) have been studied for induction of skeletal tissue growth. The growing applications of biodegradable polymer scaffolds in cell therapy and tissue engineering have been recently reviewed in several articles (81, 83, 89, 90).

SUMMARY

This is an exciting time for the development of biodegradable drug delivery platforms. The sustained delivery of drugs to the body has, practically speaking, become a reality as numerous products have passed regulatory review and proven to be commercially successful. New polymers continue to be developed while, at the same time, new therapeutic applications are being increasingly recognized.

BIOAVAILABILITY OF DRUGS AND BIOEQUIVALENCE

James T. Dalton

The Ohio State University, Columbus, Ohio, U.S.A.

Marvin C. Meyer

University of Tennessee, Memphis, Tennessee, U.S.A.

INTRODUCTION

The U.S. Food and Drug Administration (FDA) defines *bioavailability* as “the rate and extent to which the active ingredient or active moiety is absorbed from a drug product and becomes available at the site of action” (1–3). Because in practice it is rare that drug concentrations can be determined at the site of action (e.g., at a receptor site), bioavailability is more commonly defined as “the rate and extent that the active drug is absorbed from a dosage form and becomes available in the systemic circulation.” Usually bioavailability refers to the absorption of a drug from the gastrointestinal tract following oral administration of a dosage form. The dosage form may be of any type, including a solution, suspension, tablet, capsule, powder, or elixir. Bioavailability can also refer to the absorption of a drug from other routes of administration, such as intramuscular (IM) injection, transdermal patches, ointments and other topical preparations, and implants, which also require absorption prior to reaching the systemic circulation. As these routes of administration (e.g., oral, IM, and topical) deliver the drug to a site outside the vascular system, they are often referred to as routes of extravascular administration. The only route of drug administration that will always result in a bioavailability of 100% is an intravenous injection, in which the amount of drug reaching the systemic circulation is equal to the total administered dose.

The term *relative bioavailability* refers to a comparison of two or more dosage forms in terms of their relative rate and extent of absorption. If an intravenous injection is employed as the reference dose, one can determine the *absolute bioavailability* of the test dosage form. Two dosage forms that do not differ significantly in their rate and extent of absorption are termed *bioequivalent*.

In general, bioequivalence evaluations involve comparisons of dosage forms that are *pharmaceutical equivalents*. Such dosage forms are defined as “drug products that contain identical amounts of the identical active drug ingredient, i.e., the same salt or ester of the same therapeutic moiety, in identical dosage forms, but not

necessarily containing the same inactive ingredients, and that meet the identical compendial or other applicable standard of identity, strength, quality, and purity, including potency and, where applicable, content uniformity, disintegration times and/or dissolution rates” (1–3). Bioequivalence determinations may also be made for *pharmaceutical alternatives*, defined as “drug products that contain the identical therapeutic moiety, or its precursor, but not necessarily in the same amount or dosage form or as the same salt or ester. Each such drug product individually meets either the identical or its own respective compendial or other applicable standard of identity, strength, quality, and purity, including potency and, where applicable, content uniformity, disintegration times and/or dissolution rates.” In some instances, two pharmaceutical alternatives exhibit markedly different bioavailability, for example, a rapidly absorbed elixir versus a more slowly absorbed capsule. In other cases, two different dosage forms (e.g., a tablet and a capsule) may or may not exhibit very similar bioavailability.

FACTORS AFFECTING DRUG BIOAVAILABILITY

Extravascularly administered drugs must traverse several barriers to reach the systemic circulation and/or their site of action. Many studies illustrate that differences in manufacturing procedures, as well as the composition of the dosage form, can affect the bioavailability of a drug product. In addition, the bioavailability of a drug product can also be influenced by the physiology of the patient and other factors, such as the content of the gastrointestinal tract. The steps involved in the disposition of an orally administered solid dosage form and the experimental approaches that may be used to characterize them are summarized in Table 1. Factors affecting the bioavailability of a dosage form, discussed briefly here, are discussed in detail elsewhere in this encyclopedia.^a

^aSee *Absorption of Drugs*, page 8; *Biopharmaceutics*, page 156.

Table 1 Disposition and evaluation of orally administered solid dosage forms

Steps involved in disposition	Experimental approaches
Dosage form reaches stomach/intestine	Measurement of pH or scintigraphy
Dosage form disintegrates into small particles ^a	In vitro disintegration testing
Drug dissolves in gastrointestinal fluids	In vitro dissolution testing
Drug reaches gastrointestinal wall/membrane	
Drug is returned to gastrointestinal lumen by P-glycoprotein efflux pump	In vitro drug transport studies
Drug is metabolized by intestinal enzymes	In vitro drug metabolism studies
Drug is absorbed into hepatic circulation	In situ/in vivo hepatic perfusion studies
Drug reaches systemic circulation	Assay of drug in blood, plasma, or serum
Drug is excreted in urine	Measurement of drug excretion in urine
Drug is metabolized	Measurement of metabolite(s) in blood and/or urine
Drug and/or active metabolite reaches its site of action and causes a pharmacologic response	
Response is unrelated to desired therapeutic activity	Measurement of onset, duration, and intensity of pharmacologic response
Response related to desired clinical response	Determination of clinical efficacy in patients

^aSome dosage forms are designed to remain intact (e.g., certain controlled-release products).

A major factor determining the bioavailability of an orally administered drug product is the dissolution rate of the drug. A drug must be in solution in order to be absorbed from the gastrointestinal tract. Even if the drug product is administered as a solution, some dissolution process may be required in the event that the drug precipitates as a result of low solubility in the fluids of the gastrointestinal tract.

Drug Product Formulation

Most drugs are not taken as pure chemicals but are formulated into a pharmaceutical dosage form. Such drug products may be a relatively simple solution or a compressed tablet containing binders, fillers, lubricants, a coloring agent, and the like; or a controlled-release product. The following are some of the formulation and manufacturing variables that could influence the bioavailability of a drug product: 1) the properties of the drug (salt form, crystalline structure, formation of solvates, solubility); 2) the composition of the finished dosage form (presence or absence of excipients, special coatings); 3) manufacturing variables (tablet compression force, processing variables, particle size of drug or excipients, environmental conditions); and 4) rate and/or site of dissolution in the gastrointestinal tract.

Physiologic and Other Factors Affecting Bioavailability

The rate and extent of drug absorption can also be affected by a wide variety of factors related to the

characteristics of the subject/patient receiving the drug product. These factors are important to consider because they can contribute to intrasubject and intersubject variability during treatment, and, if not well controlled during the course of a bioavailability study, they can bias the results and confound interpretation of the data. Examples include: 1) contents of the gastrointestinal tract (fluid volume and pH, diet, presence or absence of food, bacterial activity, presence of other drugs); 2) rate of gastrointestinal tract transit (influenced by disease, physical activity, drugs, emotional status of subject, and composition of the gastrointestinal tract contents); 3) pre-systemic drug metabolism and/or degradation (influenced by local blood flow; condition of the gastrointestinal tract membranes; drug transport, metabolism or degradation in the gastrointestinal tract or during the first pass of the drug through the liver); 4) age, sex, race, disease, body size, time of day, and physical activity.

Other factors related to the subject, if not recognized or controlled, can also influence the assessment of drug bioavailability and product bioequivalence. For example, bioavailability studies typically involve the collection of blood and/or urine specimens to determine drug appearance in the systemic circulation. Thus, physiologic and pharmacokinetic perturbations that affect the concentration of drug measured in these fluids can potentially influence the results and interpretation of the study. Examples include changes that alter 1) the rate, extent, and/or route of metabolism (e.g., coadministered drugs that compete for or induce drug metabolizing

enzymes); 2) the rate and/or extent of drug elimination by the kidney (e.g., kidney disease and/or competition and changes in urine pH that affect renal transport mechanisms); 3) the degree of binding of the drug to plasma or tissue proteins (e.g., age-related changes in plasma binding proteins or protein binding displacements); and 4) distribution of drug into the erythrocytes. Genetic polymorphisms in the drug metabolizing enzymes of the liver may also contribute to large differences in the pharmacokinetics of a drug and the interpretation of bioavailability studies (4). A well-designed bioavailability study must either control or account for the influence of such variables.

CHARACTERISTICS OF DRUGS WITH THE GREATEST POTENTIAL FOR A BIOAVAILABILITY PROBLEM

The total number of marketed drug products known to exhibit a significant bioavailability problem is relatively small. Thus, one view is that bioavailability has been overemphasized and that for most drug products it is not a matter of concern. Another view is that those products that exhibit a bioavailability deficiency in a carefully controlled study provide ample evidence of the potential of a bioavailability problem for many drug products not yet studied.

With minor exceptions, the U.S. FDA has required that bioavailability and bioequivalence of a drug product be demonstrated through in vivo studies. However, a Biopharmaceutics Classification System (BCS) was recently proposed that divides drugs into classes based on their solubility, permeability, and in vitro dissolution rate (5). This classification system could be used to justify the waiver of the requirement for in vivo studies for “rapidly dissolving drug products containing active moieties/active ingredients that are highly soluble and highly permeable.” If adopted by the FDA, the bioavailability and bioequivalence of drug products meeting these requirements could be demonstrated using in vitro solubility, permeability, and dissolution studies. However, drugs that are poorly permeable, poorly soluble, and/or formulated in slowly dissolving dosage forms would be considered more likely to demonstrate a bioavailability problem and thus, would not be candidates for the waiver of in vivo bioavailability studies.

The U.S. FDA published a summary of evidence that may be employed to assess the importance of establishing the bioavailability of a given drug (3). The summary is as follow:

1. Data from clinical trials or bioequivalence studies indicate a bioequivalence problem.
2. The drug has a narrow therapeutic ratio, and the drug concentrations in the patient must be carefully adjusted.
3. A lack of bioequivalence could have serious medical consequences.
4. Physicochemical evidence indicates that:
 - a. the drug has low solubility in water and/or the dissolution rate of the dosage form is slow;
 - b. the particle size, crystalline structure, and other factors of the drug can affect the dissolution and bioavailability; and
 - c. the drug product contains a high ratio of excipients to active ingredients, or the product may require excipients to enhance absorption or contain excipients that inhibit absorption.
5. Pharmacokinetic evidence indicates that:
 - a. the absorption of the active drug is limited to a specific region of the gastrointestinal tract;
 - b. the extent of absorption is low;
 - c. there is rapid metabolism such that rapid dissolution and absorption are required for effectiveness;
 - d. the product required special formulations to stabilize the drug in the gastrointestinal fluids; and
 - e. the drug exhibits dose-dependent pharmacokinetics.

Drugs that meet one or more of the above criteria and have been shown to exhibit significant differences in the bioavailability of marketed dosage forms include: digoxin, quinidine, furosemide, nitrofurantoin, prednisone, chloramphenicol, theophylline, chlorpromazine, phenytoin, amitriptyline, and phenylbutazone.

EXPERIMENTAL DETERMINATION OF BIOAVAILABILITY

Types of Studies

Several methods can be used to determine the bioavailability or bioequivalence of a drug product. The vast majority of bioavailability studies involve the administration of the test dosage form to a group of healthy human subjects, followed by the collection and assay of the drug concentration in blood (plasma or serum) samples. The second most frequent method utilizes urinary excretion measurements. Occasionally, other types of biological

material, such as saliva, cerebrospinal fluid, bile, or feces are also collected. For a few drugs, for which assay methods are not available for the determination of drug concentrations in biological fluids, a pharmacologic response may be measured. Finally, some bioavailability assessments have been made on the basis of a determination of the therapeutic response of patients to a given dosage form. However, this type of study is usually restricted to drugs that are active at the site of administration (e.g., topical) but are not intended to be available in the systemic circulation. For approval by the U.S. FDA, pharmacokinetic, pharmacodynamic, clinical, and in vitro studies are recognized (in descending order of preference) as acceptable approaches to document the bioavailability or bioequivalence of a drug product.

Blood level studies

The primary basis for blood concentration studies is the assumption that two dosage forms that exhibit superimposable blood concentration time profiles in a group of subjects should result in identical therapeutic activity in patients. Figure 1 illustrates a theoretical blood concentration time curve after the oral administration of a drug product. The key parameters to note from this figure are the maximum blood concentration (C_{\max}), the time (T_{\max}) of occurrence of the maximum blood concentration, and the total area under the blood concentration time curve (AUC). The value of T_{\max} provides a means to assess the rate of absorption of the drug. The T_{\max} is independent of the amount of drug absorbed but is inversely related to the absorption rate. Thus, the faster the absorption of a drug, the shorter will be the T_{\max} . The value of T_{\max} is also influenced by the rate of elimination of the drug from the body. However, if one assumes elimination rate does not change during the period when two or more dosage forms are being tested in a given subject, then observed differences in T_{\max} will reflect absorption rate differences among the test products. The interpretation of C_{\max} is somewhat more complicated because it is a function of both the rate of absorption and the extent of absorption, as well as the elimination rate. Thus, as the amount of the drug absorbed increases and/or the rate of absorption increases, the C_{\max} also increases, assuming no change in elimination rate. A determination of the extent of drug absorption is usually based on a measure of AUC, which is directly proportional to the fraction of the administered dose that reaches the systemic circulation and is independent of the rate of absorption. The calculation of AUC is commonly accomplished using the linear trapezoidal rule (Fig. 1). The blood concentration time curve is divided into a series of geometric sections, and the

Fig. 1 Drug concentration in blood time plots illustrating calculation of C_{\max} , T_{\max} , and AUC.

area encompassed by each section is determined from the trapezoidal rule

$$\text{AUC} = 12 * (\Delta t) * (C_1 + C_2) \quad (1)$$

where Δt is the time interval between the collection of two blood samples of concentrations C_1 and C_2 . The units of AUC are given as the product of concentration and time (e.g., mg/Liter \times hr). If blood samples are not obtained for a sufficient period of time to result in a zero drug concentration in the final sample, it is necessary to estimate the portion of the AUC remaining after the final sample. Eq. 2 gives the relationship between the AUC ($0 - t$) for the portion of the curve to the last sample taken at time t , and the total AUC($0 - \infty$)

$$\text{AUC}(0 - \infty) = \text{AUC}(0 - t_{\text{last}}) + C_{\text{last}}/K \quad (2)$$

where C_{last} is the last measurable drug concentration, t_{last} is the time at which it was collected, and K is the apparent first-order elimination rate constant estimated

from the terminal slope of the log-linear plot of concentration versus time. In studies involving blood sampling intervals after the peak that are relatively long compared with the half-life of the drug, the use of the logarithmic trapezoidal method has been recommended to estimate the postpeak AUC (6).

The value of $AUC(0 - \infty)$ may also be as expressed in Eq. 3:

$$AUC(0 - \infty) = F * D / CL \quad (3)$$

where F is the fraction of dose absorbed, D is the administered dose, and CL is the total body clearance of the drug. Thus, a comparison may be made between two different dosage forms on the basis of the ratio of their respective $AUC(0 - \infty)$ values. Assuming equivalent doses are given and the clearance of the drug remains constant during the time the two doses are administered, the ratio of the AUCs will be directly proportional to the ratio of the fraction of each dose absorbed, that is, the extent of absorption.

Figure 2 illustrates the types of plasma concentration time data that might be obtained during the testing of three different bioinequivalent formulations of a drug. Products A and C are absorbed at the same rate, based on identical T_{max} values, but B is more slowly absorbed, as shown by the longer time required to achieve C_{max} . Products A and B appear to be absorbed to the same extent on the basis of very similar values for AUC. However, product C is obviously less completely absorbed, as shown by the lower AUC.

Fig. 2 Drug concentration in blood versus time after single doses of product A (rapidly and completely absorbed), product B (slowly and completely absorbed), and product C (rapidly absorbed, but only 50% as completely absorbed as products A and B).

All of the foregoing discussion assumes the absorption and elimination of the drug do not exhibit dose-dependent pharmacokinetics. For example, if the metabolism of a drug is a saturable process, the total AUC may be significantly increased for a rapidly absorbed dosage form because the initial blood drug concentrations exceed the metabolic capacity of the body to eliminate the drug. Nonlinear pharmacokinetics may also be caused by changes in the clearance of a drug due to factors such as nonlinear drug binding to plasma and/or tissue proteins. Thus, for a drug such as disopyramide, the AUC does not increase in proportion to the administered dose (7, 8). This is the result of a decrease in drug binding as drug concentration increases. Thus, it is necessary to measure free drug concentration in the plasma, rather than total drug concentration (free + bound), for disopyramide bioequivalence studies. Other mechanisms that can contribute to nonlinear pharmacokinetics and complicate the interpretation of bioequivalence data have been reviewed by Tozer and Tang-Liu (9). The interpretation of non-superimposable blood concentration time profiles for drugs that exhibit nonlinearity must be done with caution. Further, bioavailability and bioequivalence studies of such drugs may need to include multiple-dose protocols to further define the effect of differences in the rate and extent of absorption on the steady-state drug concentrations.

Urinary excretion studies

The estimation of bioavailability on the basis of the appearance of drugs in the urine is an attractive alternative to blood sampling because it represents a noninvasive method. This approach is particularly useful for drugs that have the urine as the site of activity (e.g., urinary tract antiseptics, such as nitrofurantoin and methenamine). This method is also useful for drugs that are extensively excreted unmetabolized in the urine, such as certain thiazide diuretics and sulfonamides. Often a less sensitive analytic method is required for urine concentrations compared with blood concentrations. If the urine concentrations are low, assaying larger sample volumes is relatively easy. The primary disadvantage to urinary excretion studies is that they require the collection of samples for a longer period of time to ensure the complete recovery of the absorbed drug. In addition, the subjects must be careful to completely void at each collection time and to avoid accidentally discarding any samples. As with the assessment of bioavailability from blood levels, urinary excretion studies also generally assume the pharmacokinetics are not dose dependent. If renal excretion is a saturable process, the percentage of the

drug excreted unmetabolized in the urine may not reflect the rate and extent of the drug absorption.

The three major parameters examined in urinary excretion bioavailability studies are: 1) the cumulative amount of drug excreted unmetabolized in the urine (ΣXu); 2) the maximum urinary excretion rate (ER_{\max}); and 3) the time of maximum excretion rate (T_{\max}). In simple pharmacokinetic models, the rate of appearance of drug in the urine is proportional to the concentration of drug in the systemic circulation. Thus, the values for T_{\max} and ER_{\max} for urine studies are analogous to the T_{\max} and C_{\max} values derived from blood level studies. The value of T_{\max} decreases as the absorption rate of the drug increases, and ER_{\max} increases as the rate and/or the extent of absorption increases. The value for ΣXu is related to the AUC and increases as the extent of absorption increases.

The calculation of excretion rate (ER) is based on Eq. 4

$$ER = \left(\sum Xu_2 - \sum Xu_1 \right) (t_2 - t_1) \quad (4)$$

where ΣXu_1 and ΣXu_2 represent the cumulative amount of drug recovered in the urine samples obtained at sampling times up to t_1 and t_2 , respectively. When constructing a plot of ER versus time, or for the determination of ER_{\max} , the values for time are taken to be the midpoint of the urine collection period, that is, the midpoint between t_1 and t_2 . Thus, estimates of T_{\max} and ER_{\max} from urinary excretion data provide less information on the rate of drug absorption than can be obtained from analysis of the blood concentration time profile, largely due to the fact that there is a limit to the frequency at which urine can be readily collected.

When sufficient urine samples have been collected to ensure that no significant amount of drug remains to be excreted, the cumulative urinary recovery is symbolized as $\Sigma Xu \infty$. The relative extent of absorption of drug 5 from two dosage forms may then be expressed as the ratio of the $\Sigma Xu \infty$ values. However, the value of $\Sigma Xu \infty$ is a function of the fraction (F) of administered dose (D) absorbed, the renal elimination rate constant (ke), and the rate constant for overall elimination (K) from the systemic circulation, as expressed in Eq. 5:

$$\sum Xu_{\infty} = F * D * ke / K \quad (5)$$

Assay of other biological material

For a few drugs such as theophylline, saliva drug concentrations have been employed to supplement the collection of blood samples. However, the intersubject and intrasubject variability in saliva/plasma ratios have generally precluded the sole use of saliva drug

concentrations to assess bioavailability. For some drugs such as cephalosporin antibiotics, clinical studies may also include a determination of the appearance of the drug in other body fluids, such as the cerebrospinal fluid and bile.

One might initially think that assessing the extent of drug absorption after oral administration would be possible by simply quantitating the amount of drug excreted in the feces. Such determinations occasionally provide useful data. For example, if subjects receive the drug as an enteric-coated tablet or some other solid dosage form and the product is recovered intact in the feces, there is little question regarding the lack of bioavailability. However, the data obtained from fecal recovery studies must be carefully interpreted. If the drug is analytically measured in a fecal sample, this does not establish that the drug was not absorbed. For example, certain drugs undergo extensive enterohepatic recycling and/or excretion in the saliva. Thus, a drug could be fully bioavailable, and, yet, a portion of the administered dose could be found in the feces. Further, the absence of intact drug in the feces is not proof of absorption because the drug may be degraded during its transit through the gastrointestinal tract.

Assessment of bioavailability from pharmacologic response

Topical application of a corticosteroid does not generally result in measurable blood concentrations of the drug. Thus, bioavailability and bioequivalence determinations for these drug products may involve measurement of dermatologic vasoconstriction (i.e., skin blanching), a pharmacodynamic response. A few studies have attempted to relate quantitatively a pharmacologic response to the oral bioavailability of a drug. For example, a relationship between the extent and duration of serum glucose concentration reduction and the bioavailability of two dosage forms of tolbutamide was demonstrated (10, 11). Others have employed pharmacologic end points that were not necessarily related to the therapeutic activity of the test drug. For example, attempts have been made to relate pharmacologic responses, such as changes in pupil diameter, electrocardiogram readings, or electroencephalogram readings, to the time course of a given drug in humans and animals. However, pharmacologic data tend to be more variable, and demonstrating a good correlation between the measured response and the amount of drug available from the dosage form may be difficult. Further, the potential exists that the measured response may be due to a metabolite whose concentration is not proportional to the concentration of the parent drug responsible for therapeutic activity.

Assessment of bioavailability from therapeutic response

Because the ultimate goal of drug therapy is to achieve some therapeutic response in a patient, ideally the assessment of drug product efficacy should be studied in patients requiring the drug. Nonetheless there are good reasons to utilize healthy volunteers rather than patients. First, the quantitation of patient clinical response is too imprecise to permit a reasonable estimation of the relative bioavailability of two dosage forms of the same drug. Second, bioequivalence studies are usually conducted using a crossover design in which each subject receives each of the test dosage forms, and it is assumed that the physiologic status of the subject does not change significantly over the duration of the study. If patients, however, were utilized, this could be an invalid assumption because of changes in a patient's disease state. Third, unless multiple-dose protocols were employed, a patient who required the drug for a disease would be able to receive only a single dose of the drug every few days or perhaps each week. To avoid such problems, one could test each product in different groups of patients, but this would require both the use of a large number of patients and careful matching of the various patient groups. Fourth, many patients receive more than one drug, and the results obtained from a bioavailability study could be compromised because of a drug-drug interaction. Finally, an ethical question would arise in the case in which a particular product was believed to be defective. Thus, a patient requiring treatment with a given drug would need to consent to receive a product that might not provide sufficient drug for adequate treatment. Because of these considerations, the general conclusion is that most bioequivalence studies should be carried out with healthy subjects. However, for drugs that are not designed to be absorbed into the systemic circulation and are active at the site of administration, clinical studies in patients are the only means to determine bioequivalence. Such studies are usually conducted using a parallel, rather than a crossover, design. Examples include studies of topical antifungal agents, drugs used in the treatment of acne, and agents such as sucralfate used in ulcer therapy.

Other experimental approaches

The current bioequivalence regulations of the U.S. FDA describe several types of experimental approaches that do not involve human testing (3).

Use of experimental animals: Animal studies are not acceptable for bioequivalence determinations unless the data obtained with animals have been correlated with the data obtained in human studies, ensuring that the

bioavailability of a dosage form in animals is closely related to that in humans. Animals are known to differ from humans in terms of gastrointestinal tract characteristics, metabolism, distribution, and excretion. For the study of solid dosage forms, relatively large animals, such as, dogs or monkeys, must be employed. Although such studies can provide useful data during dosage form development and may serve as an alternative to human subjects for drugs that are quite toxic to humans (e.g., cancer drugs), in general, animal studies are not acceptable as the final assessment of the bioavailability of a dosage form.

In vitro methods: In recent years, there has been great interest in the development of laboratory test systems that can simulate the disintegration and dissolution of a drug product in the human gastrointestinal tract. The development of such devices is to reduce the need for human testing. One of the early approaches to relate in vivo bioavailability data to in vitro measurements employed testing based on the time required for a solid dosage form to disintegrate in a particular solvent. The official apparatus employed for such testing is described in the U.S. Pharmacopoeia XXIV (USP) (12). However, the problem with this method is that the measurement of the time required for a dosage form to break into small particles may not necessarily relate to the dissolution rate of the drug. The current XXIV describes one official in vitro disintegration apparatus (i.e., basket-rack assembly) and two official dissolution apparatus (i.e., one with a paddle and one with a basket stirring element) for the evaluation of solid dosage forms (12). Although these methods are well-established and used extensively, few in vitro/in vivo correlations between dissolution data and human bioavailability data have been established. In vitro dissolution testing is useful as a standard for monitoring product quality and for distinguishing between dosage forms for which a bioavailability problem is known to exist. However, the USP acknowledges that many of the formulation factors that affect the performance of a drug product during in vitro dissolution testing may only sometimes affect the in vivo bioavailability of the drug (i.e., dissolution testing may identify subtle differences in the characteristics of the dosage form that are not relevant to its in vivo performance) (12). Thus, in vitro dissolution testing cannot be assumed to relate to the in vivo bioavailability of a given dosage form.

In conducting dissolution studies, the choice of an appropriate solvent is very important. Dissolution experiments should be conducted using conditions that mimic the environment in the gastrointestinal tract. Typical dissolution studies employ 0.1 *N* hydrochloric acid, water, or a buffer as the dissolution media. Simulated gastric

fluid (pH 1.2), with or without pepsin and simulated intestinal fluid (pH 6.8), with or without pancreatin, are also commonly employed for in vitro dissolution testing. It is widely recognized that the dissolution of controlled-release dosage forms may be pH-dependent. Thus, the US FDA recommends that dissolution testing for controlled-release dosage forms be conducted over a wide range of pH values, including 1–1.5, 4–4.5, 6–6.5, and 7–7.5, with multiple time determinations to better characterize the dissolution properties of the dosage form (1–3). Bioequivalence determinations for products containing cholestyramine resin (used to control cholesterol) represent a novel in vitro approach to bioequivalence testing. Generic versions of such drug products are evaluated in vitro by determining the rate and extent of the interaction of different bile salts with the resin.

Experimental Design

The proper design of a bioavailability or bioequivalence study is essential to the collection of meaningful data. Studies must include a sufficient number of subjects, and blood or urine samples must be collected at appropriately spaced intervals to characterize accurately the pharmacokinetics of the drug product(s) and make statistically relevant conclusions regarding its bioavailability and bioequivalence. Amongst other factors, study design must consider the characteristics of the study population (e.g., age, weight, gender, race, and health), the timing of dose administration, meals, and blood sample collection, and the time interval (i.e., washout period) between consecutive administrations of the drug products. In a bioequivalence study involving two or more dosage forms, the sequence of product administration must also be carefully considered to minimize experimental bias. The purpose of these rigorous controls on experimental design and conduct is to minimize the variability associated with pharmacokinetic (e.g., clearance, volume of distribution, and absorption) and physiologic (e.g., gastric emptying and pH) factors, such that the variability observed during the study is more closely related to the performance of the drug product(s) under consideration.

Crossover designs versus other designs

The most common type of study uses a crossover design in which each subject receives each of the test products. In such a design, differences among dosage forms, subjects, and sequences of administration can be readily estimated. In essence, each subject serves as his own control. Crossover designs have also been developed to minimize the effects of residual or carryover effects, which could occur if the administration of a given dosage form had an

Table 2 Three-way crossover design for bioequivalence study

Subject	Dosing period:		
	Period 1	Period 2	Period 3
1 and 2	A	B	C
3 and 4	A	C	B
5 and 6	B	A	C
7 and 8	B	C	A
9 and 10	C	A	B
11 and 12	C	B	A

influence on the bioavailability of a subsequently administered product. Table 2 illustrates a crossover design that could be employed to evaluate the relative bioavailability of three dosage forms (A, B, and C) in a group of 12 human subjects. Note that there are six possible sequences for the administration of each of the three products. Further, each subject receives each of the three products, and each dosing period contains all three products. The value of such a design is that it minimizes any bias relating to subject and dosing sequence effects. Replicate study designs, in which each subject receives the test and reference drug products on more than one occasion, are currently being evaluated as an alternative method to examine the bioequivalence of drug products.

Single-dose versus multiple-dose studies

Bioavailability studies intended to determine the disposition of a drug, particularly those involving new chemical entities, must include both single- and multiple-dose administration. However, most bioequivalence studies, which compare the bioavailability of two or more dosage forms, usually employ only single-dose administration for each product, under fasting conditions. One major exception is bioequivalence studies of controlled-release products. The U.S. FDA requires both single- and multiple-dose administration, as well as a determination of the effect of food on the absorption of the drug from the dosage form (1–3). However, the requirement of multiple dose studies in assessing the bioequivalence of controlled-release products while receiving much attention recently, may be abandoned, with the thought that single dose studies provide more sensitive information to assess the performance of these products.

Multiple-dose studies are more difficult to control, and they expose the subject to more drug. However, multiple-dose study designs also have advantages. They are more representative of how drug products are usually used by patients, and they also require fewer blood

Fig. 3 Drug concentrations in blood vs. time after multiple doses of three products administered every 6h. The products (A, B, and C) are the same as those illustrated in Fig. 2.

samples and less sensitive analytical methods. Such studies require a sufficient number of doses to permit the achievement of steady state, which may be defined as the point where the amount of drug being absorbed into the body is equal to the amount being eliminated from the body. A general rule is that dosing must continue for approximately five biological half-lives in order to be within approximately 95% of steady state. Once steady state has been reached, the area under the blood concentration time curve during a single dosing interval should be equal to the value of the AUC ($0-\infty$) from a single dose (assuming dose-independent clearance of the drug). Thus, it is necessary to obtain blood samples over only a single dosing interval at steady state in order to determine the AUC. The dosing interval selected for sampling (e.g., 7 A.M. through 7 P.M. at steady state, if dosing occurs every 12 h) should be identical for each study phase. Because the disposition of the drug could vary as a function of time of day, comparing an AUC determined during the period 7 A.M. through 7 P.M. for one product and the AUC determined from 7 P.M. through 7 A.M. for a second product would not be valid.

An example of the results of a steady-state study, with dosing every 6 h, is illustrated in Fig. 3. The pharmacokinetic data employed to generate the results shown in Fig. 3 were identical to those used for Fig. 2. The results demonstrate the influence of the rate and extent of absorption on the steady-state plasma concentrations. The lower plasma concentrations shown for product C reflect the lower extent of absorption for this product. Products A and B have the same extent of absorption but differ in rate of absorption. Product A is more rapidly absorbed than product B, and, thus, there is a greater fluctuation between the maximum and minimum concentrations at steady state.

Other study design considerations

In the design or evaluation of the results of a bioavailability or bioequivalence study, it is important to establish that an adequate number of subjects were studied and that an adequate number of blood and/or urine samples were collected. As in most scientific studies, the use of too few subjects precludes reaching meaningful decisions regarding the significance of differences that may be observed. Moreover, values for T_{\max} , C_{\max} , or ER_{\max} cannot be accurately determined if the time interval between samples is too great. Further, accurate estimates of AUC and/or total urinary recovery of drug are not possible if blood and/or urine collections are terminated prematurely. As a general rule, collecting blood samples for at least two to three biological half-lives is desirable, and urinary excretion studies should include urine collections for five to seven biologic half-lives. Some extension of these guidelines may be necessary if the study involves controlled-release dosage forms that may result in absorption for a prolonged period. If data are not available for the half-life of a drug, a reasonable guideline is to continue blood sampling until blood concentrations have declined to less than 10% of the peak concentrations. Similarly, urine collections should be continued until significant quantities of drug are no longer being excreted. A typical bioavailability study utilizes from 12 to 24 or more healthy subjects who have no history of any disease that could affect the disposition of the test drug. The subjects are required to refrain from taking any drug other than the test compound for a period (usually one week or more) prior to the study and throughout the course of the study. Certain drugs, such as, enzyme inducers, could affect the disposition of the test drug. Further, depending on the specificity of the assay, other drugs may interfere in the quantitation of the drug of interest. Usually, only subjects between the ages of 18 and 40 are employed, unless there are specific reasons for employing other subject populations. Both male and female subjects should be included in the study, as well as subjects of differing race, realizing, of course, that the heterogeneity that one may accommodate in a study of 12 subjects is limited if statistically meaningful comparisons are to be made between the groups. Finally, for typical single-dose studies, the subjects are required to fast from approximately 12 h before the dose until 4 h after the dose, unless the objective of the study is to determine the influence of food on absorption of the drug.

Analytical methodology

One of the most important considerations in any bioavailability study is the validity of the analytical

method. In addition to being reproducible, it must be sufficiently sensitive to permit the detection of low drug concentrations in the biologic sample. After single-dose administration, drug concentrations in plasma are frequently in the low microgram or nanogram per milliliter range. Further, the method must be specific for unmetabolized drug and be capable of accurately determining drug concentrations in the presence of metabolites of the drug and the constituents of blood and/or urine. Most analytical methods involve some type of clean-up step, such as, solvent extraction, to separate the drug from the biological fluid. In addition, most assays employ some type of chromatography, often using either gas chromatography or high-performance liquid chromatography. Assay validation is a critical component of any bioavailability or bioequivalence study and should consider the accuracy, precision, sensitivity, specificity, linearity, and reproducibility of the analytical method. In the biologic sample, the stability of the drug during storage must also be given careful consideration.

Analysis and Interpretation of Data

Bioequivalence studies are usually intended to demonstrate that two or more formulations do not differ significantly (i.e., that the products are therapeutically equivalent and interchangeable). Once the data from a bioequivalence study are collected, statistical methods must be applied to determine the level of significance of any observed differences. Statistical comparisons of the C_{\max} and AUC are performed after log transformation. Log transformation is appropriate because 1) many biological and pharmacokinetic parameters are log-normally distributed, and 2) it is the ratio of C_{\max} and AUC between drug products, and not the absolute difference between the mean values, that is most relevant for comparison. Also, one-sided statistical tests at a 0.05 level of significance are performed using the log-transformed data from the bioequivalence study. It is important to note that 90% confidence intervals (CIs), and not the mean values, of C_{\max} and AUC are employed to make this comparison and assure the bioequivalence of the drug products. In other words, the 90% CI for the mean C_{\max} and mean AUC for the drug product must be between 80 and 125% of the respective mean values for the reference dosage form (e.g., a drug product with a mean C_{\max} of 83% of the reference product with a 90% CI of 79–87% would not be considered bioequivalent). In fact, if the mean C_{\max} or mean AUC of the drug product differs by more than 10–15%, the CI is likely to fall outside the 80–125%

range. Typically, an analysis of variance (ANOVA) method appropriate for the study design is applied to evaluate differences among dosage forms, subjects, and treatment periods. Mean T_{\max} values are also computed, but unless large differences are observed, they are generally not used for the bioequivalence determination, largely due to the fact that T_{\max} values are highly dependent on study design and the time at which blood samples were collected.

SUMMARY

The measurement of the bioavailability and bioequivalence of drug dosage forms is commonplace. The numerous reasons for the increased use of such studies include: 1) rapid growth of the generic drug industry; 2) an increased awareness of the effect of dosage form on the rate and extent of drug absorption; 3) the development of more sensitive and reliable analytic methods to quantitate drugs and metabolites in the body; and 4) the need to have a means to evaluate the vivo performance of a dosage form by a means other than clinical trials in patients. Clearly, bioavailability and bioequivalence studies have become a routine part of the drug product approval process by governmental agencies. Such studies provide valuable information regarding the disposition of a drug in humans and the factors that may influence its performance. These data are useful in the development of new dosage forms and assist in the preparation of appropriate labeling for a drug product. Finally, bioequivalence studies have become an essential part of the comparison of pharmaceutically equivalent products manufactured by different pharmaceutical firms.

BIOTRANSFORMATION OF DRUGS

L.F. Chasseaud

D.R. Hawkins

Huntingdon Life Sciences, Huntingdon, United Kingdom

INTRODUCTION

The term *biotransformation of drugs* can be defined as the chemical conversion of drugs to other compounds in the body. However, this definition excludes degradation due to any inherent chemical instability of drugs in biological media. These conversions are usually mediated by enzymes in the body's organs, tissues, or biofluids, but occasionally they may occur by nonenzymic reactions and even by a combination of both enzymic and nonenzymic processes. Synonymous with biotransformation in this context is the word *metabolism*, and indeed the terms *drug biotransformation* and *drug metabolism* are used to describe the same events and are often interchanged, seemingly somewhat randomly. If anything, the latter is the more popular term.

Compared to the established scientific disciplines, the study of the biotransformation of drugs constitutes a relatively new subject area: the earliest scientific papers are little more than a century old. Regarded by many as a branch of pharmacology, drug biotransformation more properly belongs to biochemistry. However, knowledge of the biotransformation of drugs often contributes, in no small way, to a better understanding of pharmacologic, toxicologic, and clinical phenomena, and papers on drug biotransformation are to be found in journals specializing in these other subjects as well as those of biochemistry and chemical analysis. In the last three decades, exponents of drug biotransformation have created their own journals and review series.

A leading pioneer in drug biotransformation research was the late R.T. Williams, who wrote *Detoxication Mechanisms*, the first major text on the subject published over 40 years ago, and a classic to this day. Subsequently, the literature on drug biotransformation grew steadily until recent years, when it seems to have expanded almost exponentially. The major driving forces for this proliferation include the realization of the importance of drug biotransformation knowledge in promoting a better understanding of certain pharmacologic, toxicologic, and/or clinical findings; governmental legislation requiring drug biotransformation studies as part of new chemical entity safety evaluation programs; major advances in the

necessary scientific instrumentation; and the commercial availability of isotopically labeled compounds whose use can greatly facilitate drug biotransformation studies.

Because this article deals mainly with concepts, citation of specific scientific references is deliberately avoided. The reader is referred, instead, to the monographs referenced in the bibliography for a lead into more detailed or earlier scientific literature.

NEED FOR DRUG BIOTRANSFORMATION

During their lives, humans take a wide, almost infinite variety of substances into their bodies, some of which are necessary for their well-being and provide the raw materials essential for the processes of intermediary metabolism. However, other substances which the body does not require are also ingested, inhaled, or absorbed; these substances have been described as *exogenous compounds*, *foreign compounds*, or *xenobiotics* (Greek *xenos* = foreign) and can be either naturally occurring or man-made. The physicochemical properties (e.g., lipid solubility) that enable these compounds to be absorbed readily into the body would tend to preclude their facile excretion. Consequently, they would accumulate in the body and eventually cause deleterious effects. As a counter, metabolic processes have been adapted during evolution to deal with foreign compounds by converting (biotransforming) them into derivatives of great polarity (i.e., water solubility) that are consequently more easily excreted. Drugs are one type of foreign compound that the body usually has to biotransform in order to effect their removal. The action of many drugs is curtailed by biotransformation. With some drugs, however, biotransformation results in metabolites that share the pharmacologic action of the parent drug or may even exhibit other properties. The polynitrated organic nitrate vasodilators, such as isosorbide dinitrate, have metabolites that, as long as they contain nitrate groups, can exert the antianginal action of the parent drug, albeit at lower potency. Metabolites of benzodiazepines, such as diazepam, also possess its anxiolytic properties, and one of its metabolites, temazepam, is used

as a hypnotic. Yet others (prodrugs) rely on biotransformation to generate the pharmacologically active agent. The depot antipsychotics are of this type; haloperidol decanoate relies on ester hydrolysis in the body to release the active drug, haloperidol.

PATHWAYS OF BIOTRANSFORMATION

Biotransformation pathways have been classified under the headings of Phase I and Phase II reactions. The former includes processes involving oxidation, reduction, and hydrolysis that result in the formation of new functional groups in the drug molecule. Many of the metabolites formed are then able to participate in a subsequent biotransformation process (Phase II) in which a polar hydrophilic moiety such as glucuronic acid, sulfate, or an amino acid is covalently linked (conjugated) to the functional group introduced in the Phase I reaction. The usual overall result of these processes is the production of metabolites with progressively greater water solubility that facilitates their removal from the body. Biotransformations are generally catalyzed by enzymes present in the liver and other tissues. Some researchers consider that the biotransformation by the gut flora of drug metabolites excreted in the bile represents a third phase.

Many drugs undergo a series of biotransformations, and the combinations of consecutive Phase I and Phase II reactions can produce a complex array of metabolites (Fig. 1). Drugs already containing appropriate functional

groups can undergo Phase II reactions without the need for Phase I biotransformation; examples are the arylacetic and arylpropionic acid anti-inflammatory drugs (e.g., indomethacin and ibuprofen respectively), in which the carboxylic acid function can conjugate with glucuronic acid or amino acids such as glycine.

In some cases, Phase I metabolites may not be detected, owing to their instability or high chemical reactivity. The latter type are often electrophilic substances, called *reactive intermediates*, which frequently react nonenzymically as well as enzymically with conjugating nucleophiles to produce a Phase II metabolite. A common example of this type is the oxidative biotransformation of an aromatic ring and conjugation of the resulting arene oxide (epoxide) with the tripeptide glutathione. Detection of metabolites derived from this pathway often points to the formation of precursor reactive electrophilic Phase I metabolites, whose existence is nonetheless only inferred.

Certain biotransformation processes are reversible, and formation of an inactive metabolite that can be converted back to the active drug delays the removal of the drug from the body and probably prolongs the duration of exposure of the target tissues to the drug. The common processes that can contribute to this phenomenon are oxidation/reduction of secondary alcohols/ketones, sulfides/sulfoxides, and tertiary amines/N-oxides, all of which are reversible processes.

The pathways of biotransformation that a given drug follows are determined by many factors, including lipophilicity, molecular size and shape, steric and electronic characteristics, stereochemistry, acidity, and basicity. The interrelationships between these factors are not well understood, as judged by the present inability to predict biotransformations accurately except perhaps within a narrow group of closely related compounds. This inability is primarily due to the limited depth of available background information and insufficient knowledge of the factors affecting the interaction of compounds with the active sites of enzymes responsible for biotransformation. The knowledge of biotransformation processes is continually increasing, and new pathways are still being discovered.

OXIDATION

Oxidation is the most commonly encountered biotransformation process, and few drugs undergo a Phase I reaction that does not involve it. Oxidation occurs most frequently at saturated (sp^3) or unsaturated (sp^2) carbon

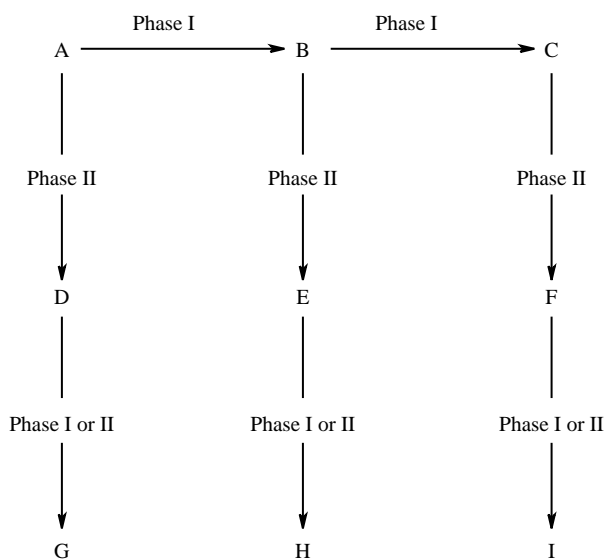

Fig. 1 Biotransformation of drug A by Phase I and Phase II reactions to several types of metabolite (B through I).

and with different valency states of nitrogen and sulfur present in either acyclic or cyclic structural environments.

Oxidation tends to decrease lipophilicity by the introduction of hydrophilic functional groups forming metabolites that may be more readily excreted. In addition, many of these functionalized metabolites are also substrates for Phase II conjugation reactions.

The nonspecific oxidation of drugs comprising many different chemical classes is catalyzed by a multienzyme mixed-function oxygenase system involving cytochrome P450 as the terminal oxidase. It is located in the endoplasmic reticulum of cells. Cytochrome P450 is a multigenic family of heme proteins, that can be distinguished from each other by their chromatographic and immunologic behavior, as well as by substrate specificity. The mechanisms of cytochrome P450 catalysis has not been established unequivocally, but a generally accepted scheme is shown in Fig. 2. The cytochromes P450 are the most versatile and extensively studied of the enzyme systems responsible for drug biotransformation.

After binding of the substrate to oxidized cytochrome P450, a one-electron transfer from NADPH is catalyzed by a flavoprotein reductase. Molecular oxygen combines with the reduced enzyme-substrate complex to form a ternary complex that accepts a second electron, possibly derived from NADH via cytochrome b_5 . One oxygen atom is transferred from the activated oxygen to the substrate to

form the oxidized product. Water and oxidized cytochrome P450 also result.

Other mono-oxygenases are not cytochrome P450 dependent, such as flavoproteins located in the endoplasmic reticulum that are involved in the oxidation of tertiary amines to N-oxides and of various sulfur compounds. Yet other oxidative enzymes, including alcohol and aldehyde dehydrogenases and monoamine oxidases, are located in the mitochondria or cytosol.

Aliphatic Carbon

Oxidation of primary (Eq. 1), secondary (Eq. 2), or tertiary (Eq. 3) carbon atoms all occur to give the corresponding alcohols. Further oxidation of a primary alcohol yields the aldehyde, which is usually rapidly converted to the carboxylic acid. The oxidation of secondary alcohols to ketones generally leads to less hydrophilic metabolites and is less common.

Metabolites derived by loss of an alkyl or arylalkyl group from ethers (Eq. 4), thioethers (Eq. 5), amines (Eq. 6), and amides (Eq. 7) represent common biotransformation pathways ($\text{R}', \text{R}'' = \text{H}$, alkyl or aryl). These processes involve oxidation on carbon adjacent to the heteroatom. The intermediates are generally unstable and readily decompose to the corresponding alcohol, thiol, amine, or amide and an aldehyde. Intermediates formed from amides (Eq. 7) are more stable and may be detected as excreted metabolites. If a secondary carbon atom is adjacent to the heteroatom, then this portion of the molecule is released as a ketone. The heteroatom may also be located in a cyclic structure (e.g., morpholine, piperazine). Two processes have been adopted for amines, namely, N-dealkylation or deamination, that are essentially the same event. In general, which of the two terms applies depends on the side of the C—N bond

Fig. 2 Postulated mechanism of cytochrome P450 catalysis. Net reaction: $\text{Substrate} + 2\text{e}^- + 2\text{H}^+ + \text{O}_2 \rightarrow \text{substrate} - \text{O} + \text{H}_2\text{O}$.

that is of greatest concern, that is, whether interest is focused on the formation of the carbonyl compound or the amine. For a primary amine, therefore, the process is termed *deamination* because the fate of the ammonia generated is of no interest. For amines, the intermediate hydroxylated products may be oxidized further to a carbonyl function, resulting in formation of amides (Eq. 6). Cleavage of esters can also occur by an oxidative process of this type (Eq. 8). The only difference compared to hydrolysis is that instead of forming an alcohol, this part of the molecule is released as an aldehyde.

Aromatic and Unsaturated Hydrocarbons

Double bonds in unsaturated hydrocarbons are oxidized by epoxidation. The resultant epoxides are generally reactive substrates that are biotransformed further to alcohols or glycols through the action of epoxide hydrolases.

Hydroxylation of aromatic compounds to phenols has long been considered an important detoxication process, particularly as phenols can conjugate readily with glucuronic acid or sulfate to give highly water-soluble

metabolites, that are excreted. The oxidation process can involve formation of arene oxide intermediates in which an aromatic double bond has undergone epoxidation. These epoxides are generally unstable and considered to be reactive intermediates. Phenols, nominally the major product of aromatic hydroxylation, do not necessarily require formation of intermediate epoxides. Epoxides can give rise to several different types of metabolites by spontaneous isomerization to phenols, enzymic hydration to dihydrodiols and conjugation with glutathione (GSH) (Fig. 3). The pattern of metabolites depends in part on the intrinsic reactivity of the epoxide. Epoxides can also react with a variety of other biologic nucleophilic centres in cellular macromolecules, such as DNA, RNA, and proteins; this may ultimately produce toxic effects. Other aromatic ring systems are also hydroxylated via postulated epoxide intermediates, the best known being furans. The site of oxidation in an aromatic ring is dependent on the type of cytochrome P450 involved and on electronic and steric factors associated with the substrate structure. For substituted aromatic compounds, each epoxide can give rise to two isomeric phenols. Thus, methsuximide forms both a dihydrodiol and two isomeric phenols in animals and humans.

The dihydrodiols may be reduced to catechols through the action of dihydrodioldehydrogenase. Catechols can also be formed by two sequential hydroxylations. These catechols can be monomethylated by catechol

Fig. 3 Biotransformation of an aromatic hydrocarbon to an epoxide that undergoes various other reactions.

O-methyltransferase, and are often the terminal metabolites formed from this pathway.

A rather novel biotransformation that can occur as part of an aromatic hydroxylation process has been called the NIH shift whereby a substituent such as bromo, chloro, and fluoro at the position of hydroxylation undergoes migration to the adjacent position. Relevant examples are relatively few but this may be due to the lack of rigorous identification of ring-hydroxylated metabolites.

Sulfur

Oxidation of divalent sulfur atoms in thioethers is a common biotransformation of sulfur-containing compounds (Eq. 9). Oxidation proceeds in two stages, first to the sulfoxide and then to the sulfone. Sulfoxides have increased polarity and are often observed as excreted metabolites, but they can also be reduced back to the sulfide. Formation of the sulfoxide creates an asymmetric center, and stereospecific oxidation can occur. Sulfones tend to be terminal metabolites; no evidence for their reduction exists.

Thioethers can be cleaved to thiols that may be converted to stable oxygenated compounds, such as sulfinic and sulfonic acids, that are highly water-soluble and readily excreted. Thiols may be oxidized first to disulfides, in which further oxidation of sulfur then occurs before cleavage to sulfinic and sulfonic acids (Eq. 9).

The thiocarbonyl group in compounds such as thioamides is biotransformed by oxidative attack on sulfur. Sulfoxidation of the thioamide occurs first and is followed by further S-oxidation to give an unstable intermediate that is readily hydrolyzed to the amide and thiosulfate (Eq. 10).

Nitrogen

N-oxidation can occur in a number of ways to give either hydroxylamines from primary and secondary amines (Eqs. 11 and 12), hydroxamic acids from amides, or N-oxides from tertiary amines (Eq. 13). The enzyme systems involved are either cytochrome P450 or a flavoprotein oxygenase. Hydroxylamines may be further oxidized to a nitro compound via a nitroso intermediate (Eq. 11). Oximes can be formed by rearrangement of the nitroso intermediate or N-hydroxylation of an imine, that could in turn be derived by dehydration of a hydroxylamine (Eq. 11). N-Oxides may be formed from both tertiary arylamines and alkylamines and from nitrogen in heterocyclic aromatic systems, such as a pyridine ring.

REDUCTION

Reductive biotransformation processes are less common than those involving oxidation, but a number of functional groups are susceptible to reduction. Some may occur non-enzymically through the action of biologic reducing agents. Certain processes are part of a reversible oxidoreductase

system, and the direction in which the equilibrium lies depends on the properties of the oxidized and reduced products. Reductive processes are favored by anaerobic conditions, and besides the action of reductases in tissues such as liver, kidney, and lung, micro-organisms in the anaerobic environment of the intestinal tract may produce reduced metabolites that are subsequently absorbed. Because reduction may often lead to metabolites of equivalent or greater lipophilicity than the precursor, it is seldom the only process occurring before a metabolite is excreted.

Carbon

Numerous ketones serve as substrates for alcohol dehydrogenases. These include alicyclic and arylalkyl ketones (Eq. 14).

Unlike aldehydes, ketones are essentially unreactive, apart from being reduced when the equilibrium shifts predominantly to the secondary alcohol that is readily conjugated, thereby encouraging further reduction of the ketone (Eq. 14). If ketone reduction results in the formation of an asymmetric carbon, a high degree of stereospecificity often occurs, even though the enzyme systems demonstrate a low degree of substrate specificity.

Alcohol dehydrogenase catalyzes the oxidation of primary alcohols to aldehydes, as well as the reverse reaction. However, due to the facile oxidation of aldehydes to acids, the reaction equilibrium is driven to the right (Eq. 15).

Thus administration of an aldehyde invariably results in the appearance of the corresponding acid as an excreted metabolite, although in some instances both the acid and alcohol are formed. Thus the aldehyde formed by deamination of the antihistamine chlorpheniramine is metabolized to a mixture of the corresponding acid and alcohol.

Reduction of carbon-carbon double bonds that may be instigated by gut flora has been observed.

Nitrogen

The types of nitrogen-containing compounds that are most frequently involved in reductive biotransformation are

those containing nitro, azo, and N-oxide functional groups. Similar enzymes are involved that are generally located in the endoplasmic reticulum or cytosol of the liver or in the intestinal microflora. Complete reduction of a nitro compound to the primary amine involves a six-electron transfer and proceeds through nitroso and hydroxylamine intermediates (Eq. 16).

Additional free-radical intermediates, such as the nitro anion radical and hydronitroxide radical, involving one-electron transfers have also been proposed. The benzodiazepine nitrazepam is reduced by liver microsomes to the corresponding amine. However, reductions involving NADPH-cytochrome c reductase may form only the hydroxylamine. A high level of nitroreductase activity is associated with anaerobic bacteria in the gut, that are capable of reducing aromatic nitro compounds to the corresponding amines. When the nitro group is located adjacent to a heteroatom in a heterocyclic ring, reduction to the nitroso or hydroxylamine intermediates often leads to cleavage of the ring. The hydroxylamine function in hydroxamic acids can also be reduced to the corresponding amides.

Aliphatic and aromatic tertiary amine N-oxides can be reduced to the corresponding amines. Reduction can occur either in liver cytosol, endoplasmic reticulum, or mitochondria, in extrahepatic tissues such as the kidney and lung, or by the gut flora.

Azoreductase activity is present in both the endoplasmic reticulum and the cytosol of the liver. It is thought to produce the hydrazo intermediate that is cleaved to give two primary amines. The best known example is that of the azo dye Prontosil that is cleaved to form sulfanilamide, an active antibacterial compound, a reaction that involves a four-electron transfer.

Certain halogenated hydrocarbons such as halothane, undergo reductive dehalogenation.

Sulfur

Most functional groups bearing sulfur, other than thiols, are primarily metabolized by oxidative processes. However, sulfoxides can be reduced to sulfides. The anti-inflammatory drug sulindac is reduced to the sulfide, which is an active metabolite, and it can be oxidized back to the sulfoxide. Disulfides are reduced to the corresponding sulfides.

HYDROLYSIS

Other important Phase I drug biotransformation reactions are those involving hydrolytic processes. The types of groups hydrolyzed include esters (Eq. 17), amides (Eq. 18), thioesters (Eq. 19), hydroxamates (Eq. 20), oximes (Eq. 21), carbamates (Eq. 22), hydrazides (Eq. 23), organophosphates (Eq. 24), and perhaps even nitriles (Eq. 25).

The hydrolytic reactions are mostly catalyzed by carboxylesterases although other names may be used for the enzymes involved depending on the substrates concerned, for example, amidases (Eq. 18), or phosphatases (Eq. 24).

With the increasing number of peptides being synthesized as potential drugs, mention should be made of peptidases that cleave (by hydrolysis) the amide (peptide) linkage between adjacent amino acids.

The carboxylesterases are a family of somewhat nonspecific enzymes that are not easily classified. They have an endogenous role in, for example, transport. B-esterases (serine hydrolases) are those sensitive to inhibition by organophosphates such as paraoxon that esterify a serine residue at the enzymes' active site; they are present in most mammalian tissues and biofluids such as the plasma. Other esterases are A-esterases (arylesterases) and the C-esterases (acetyl esterases). Esterase activity is particularly high in the endoplasmic reticulum of the liver. Some esterase activity appears to be tissue and species specific. The latter can lead to marked species differences in ester half-lives in the body, ranging, for example, from only a few minutes in the rat to several hours in the dog. Because both these species are commonly used in drug evaluation, their comparison with humans becomes of paramount importance when ester-containing drugs are being assessed. The specificity of carboxylesterases appears to depend on the nature of the substituents (R, R', R'') rather than on the type of heteroatom (O, S, or N) attached to the carbonyl group. Usually esters are hydrolyzed more rapidly than the corresponding amides, and this difference can be exploited in drug design; the duration of action of ester-containing drugs eliminated by hydrolysis could be prolonged by replacement of the ester with the amide link. The hydrolysis of an ester or amide link is usually associated with detoxication of the drug because of the greater water solubility and thus more facile excretion of the resultant hydrolysis products. However, exceptions exist; for example, salicylic acid produced by the hydrolysis of acetylsalicylic acid is still pharmacologically active and has a longer half-life than the parent drug.

The hydration of epoxides (Eq. 26) can be viewed as a special form of hydrolysis in which the elements of water are added to the epoxide without the resultant formation of more than one product, such as occurs in most hydrolytic reactions. This reaction is catalyzed by epoxide hydrolase.

Epoxides are usually chemically quite reactive as a consequence of the strain inherent in the 3-membered cyclic ether ring and the electrophilic nature of the ring's carbon atoms. Through the action of epoxide hydrolase (epoxide hydrase, epoxide hydratase), they react stereoselectively with water to produce vicinal diols that are predominantly in the *trans* configuration (Eq. 26) because nucleophilic attack by OH^- , at the least hindered carbon atom, occurs from the opposite side of the molecule to where the epoxide ring is situated. Although the diol is less reactive than the parent epoxide, it may serve as a substrate for further epoxidation elsewhere, particularly in large hydrophobic molecules such as polycyclic aromatic hydrocarbons in which it leads, for example, to the formation of highly toxic dihydrodiol epoxides resistant to epoxide hydrolase.

Epoxide hydrolase activity is present in most mammalian tissues and is high in the endoplasmic

reticulum and cytosol of the liver. Humans appear to have considerable intersubject variability in the activity of epoxide hydrolase that may impact on individual susceptibility to the toxic action of certain epoxides: This variability argues for the existence of several epoxide hydrolases.

Some epoxides are resistant to epoxide hydrolase: Carbamazepine, for example, is metabolized to an epoxide that survives biotransformation and is excreted in urine.

CONJUGATION

Phase II drug biotransformation involves reaction (conjugation) of a range of functional groups with endogenous compounds (Table 1). The resultant product is usually more water soluble than its precursor and is thus more readily excreted in the urine or bile. However, some fatty acid conjugates are more lipid soluble than the parent compound. Ester conjugates of the alcohol function of tetrahydrocannabinol and etofenamate with palmitic and other fatty acids have been identified as metabolites in feces and tissues. Although they are only minor metabolites in excreta,

Table 1 Common conjugation reactions

Reaction	Enzyme system	Functional group involved
Glucuronidation	Glucuronyltransferase	—OH —COOH —NH ₂ —SO ₂ NH ₂ —NHOH —SH
Sulfation	Sulfotransferase	—OH —NH ₂ —SO ₂ NH ₂ —NHOH
Glutathione conjugation	Glutathione S-transferase	Electrophilic center
Acetylation	Acetyltransferase	—OH —NH ₂ —SO ₂ NH ₂ —NHNH ₂ —NHOH
Amino acid conjugation	Acyltransferase	—COOH
Methylation	Methyltransferase	—OH —NH ₂ —SH

their high lipid solubility may make them of greater importance in tissues.

Conjugation reactions are catalyzed by group-transferring enzymes.

Glucuronidation

Glucuronidation is quantitatively the most important of the conjugation reactions. It can take place in most body tissues, presumably because the endogenous substrate required—uridine diphosphate *D*-glucuronic acid (UDP-GA)—is produced during intermediary metabolism by processes related to glycogen synthesis (Fig. 4). Therefore, this substrate is less likely to be depleted than those serving other conjugation reactions. Glucuronidation is catalyzed by a family of enzymes, the UDP-glucuronosyl-transferases (glucuronyltransferases); these enzymes are located mainly in the endoplasmic reticulum and are mostly tightly associated with it. An unusual property of these enzymes is their apparent latency, whereby full enzymic activity (in vitro) is expressed only after treatment with agents (e.g., surfactants) that disrupt membrane structure.

Fig. 4 Formation of uridine diphosphate glucuronic acid (UDP-GA) and its conjugation with clofibric acid. Inversion takes place during conjugation, the α -*D*-glucuronic acid forming a β -*D*-glucuronide. At a more alkaline pH, such glucuronides may undergo intramolecular rearrangement to forms resistant to enzymic hydrolysis by β -glucuronidase.

Glucuronidation can occur with alcohols and phenols (ether glucuronides are formed), carboxylic acids (ester glucuronides are formed), amines, sulfonamides, hydroxylamines, thiols, amides, carbamates, and even certain compounds containing nucleophilic carbon atoms, such as phenylbutazone. Glucuronidation of tertiary amines yields conjugates containing a quaternary nitrogen. Besides foreign compounds, glucuronidation of endogenous substrates, such as steroids, catechols, bilirubin, and thyroxine also takes place.

Less commonly, conjugation with other sugars such as glucose, ribose or xylose can occur, and for example, glucosides are formed following conjugation with UDP-glucose.

Sulfation

Sulfation is an important conjugation reaction that, like glucuronidation, requires a “high-energy” or “activated” endogenous substrate, 3′-phosphoadenosine-5′-phosphosulfate (Fig. 5); however, owing to its lower cellular concentrations, this substrate is more easily depleted than that utilized in glucuronidation. Thus, sulfation is a readily saturable biotransformation process. Where sulfation and

Fig. 5 Formation of 3′-phosphoadenosine-5′-phosphosulfate (PAPS) and its conjugation with acetaminophen (paracetamol). Strictly, the process is one of sulfonation because the $-\text{SO}_3^-$ group is being transferred.

Fig. 6 Toxic metabolite formation mediated via sulfation.

glucuronidation compete, the former tends to predominate at low substrate concentrations and the latter at high concentrations. Depending on the substrate, sulfation occurs in most tissues in the body and is catalyzed by a family of enzymes, the sulfotransferases, that are located in the cytosol.

Alcohols, phenols, hydroxylamines, and amines can be sulfated, as can endogenous substrates such as steroids, polysaccharides, and biogenic amines. Sulfation can lead to metabolites that are more toxic than their precursors (Fig. 6).

Glutathione Conjugation

Compounds possessing a sufficiently electrophilic center can conjugate readily with the endogenous nucleophile and tripeptide, glutathione (GSH). Although this reaction can proceed nonenzymically, it is usually catalyzed by the glutathione S-transferases, a group of nonspecific enzymes with overlapping substrate specificities that can also serve as binding proteins.

The electrophilic center may already be present in the compound, or it may arise as a consequence of Phase I biotransformation, as in epoxides. Conjugations with GSH may be classified broadly as replacement (substitution; Eq. 27) or addition (Eq. 28; R' = electron-withdrawing group) reactions. With the latter type in particular, new asymmetric centers are created, but only recently has the stereochemistry and stereospecificity of the reaction begun to attract interest.

GSH exerts an important protective function in the body, and conjugation with GSH generally results in

detoxication, although the chemical nature of certain substrates can facilitate the formation of a toxic conjugate (for example, Eq. 29; X = halogen).

The glutathione S-transferases appear to be present in almost all vertebrate species and their tissues, although certain isoenzymes may exhibit tissue and/or species specificity. Concentrations of the enzymes in certain tissues, such as the liver, are relatively high. They are located primarily in the cytosol but may also be present in other cell structures; those in the endoplasmic reticulum are activated by sulfhydryl reagents. Although GSH is relatively abundant in tissues (for example, about 5mM in liver), it can be severely depleted by large doses of certain drugs; in the case of acetaminophen, depletion leads to hepatotoxicity through a reactive intermediate (a quinoneimine) that is detoxified at clinical doses by conjugation with available GSH. Thus GSH conjugation is a saturable pathway.

GSH conjugates are excreted in bile but almost never in urine. Instead, they are catabolized by removal of the glutamyl and glycine moieties to yield cysteine conjugates, that may be N-acetylated and excreted in urine or in bile as N-acetylcysteine conjugates (mercapturic acids) or metabolites thereof, such as sulfoxides. The conjugates may be subjected to the action of a C-S lyase that enables methylation of the resulting thiol and subsequent oxidation of sulfur to yield the sulfoxide and sulphone. (Eq. 30).

Acetylation

The acetylation of amino groups is a fairly common reaction utilizing acetylcoenzyme A; it is catalyzed by cytosolic N-acetyltransferases. With a substrate such as sulfanilamide (Eq. 31), even diacetylation is possible. Acetylation occurs in the liver and in many other tissues.

(31)

The products of acetylation may be more or less toxic than the precursor. In the case of certain sulfonamides, the less water-soluble acetylsulfonamides can cause renal toxicity owing to their precipitation in the kidney.

Acetylation exhibits a well-known pharmacogenetic difference in the human population that is bimodal (fast or slow) and perhaps even trimodal. This difference accounts for the greater toxicity of certain drugs in either fast or slow acetylators, depending on whether the parent drug or its acetyl derivative is the more toxic entity.

Transacetylation to an acceptor containing an amino group has also been reported; it is enzyme catalyzed.

Amino Acid Conjugation

Another type of acylation involves the conjugation of drugs containing the carboxyl group with amino acids; this process occurs through a coupled system involving the formation of a high-energy intermediate of the carboxylic acid catalyzed by acyl-CoA synthetases, followed by acyl transfer to the amino acid (Eq. 32) catalyzed by acyltransferases. In mammalian species, the amino acids most utilized are glycine, taurine, glutamine, and carnitine. This conjugation occurs extensively in the hepatic mitochondria, but the enzyme systems involved have yet to receive the sort of detailed attention accorded other pathways.

(32)

Amino acid conjugation is complementary to glucuronidation. Some carboxylic acids undergo both types of reaction, whereas others undergo predominantly one type.

Methylation

Although methylation reactions are mainly concerned with endogenous substrates, a number of drugs are also methylated (Eq. 33) by nonspecific methyltransferases that are present in the liver, lung, and other tissues. The enzymes are located mostly in the cytosol, but they may also be membrane-bound. The principal methyl donor is S-adenosylmethionine (SAM) which is formed from ATP and L-methionine.

(33)

The relative importance of O-methylation in the meta or para positions (Eq. 33) appears to depend on the nature of the substituent R. Methylation usually results in the formation of a less water-soluble product, but it is often regarded as a detoxication process. S-methylation is common and, N-methylation, and the methylation of certain metals (e.g., mercury) also occur.

STEREOSELECTIVE AND STEREOSPECIFIC BIOTRANSFORMATION

Many drugs contain one or more asymmetric centers, and thus consist of a mixture of enantiomers or diastereoisomers. For each asymmetric center, there is a pair of enantiomers in a mirror-image relationship. Both pharmacologic activity and biotransformation usually require interaction of the drug with specific receptors or enzymes that can be highly stereoselective according to

the steric configuration at the site of interaction. Hence, a pair of enantiomers may differ in biologic activity and rates of biotransformation. The latter results in stereoselective pharmacokinetics, thereby also influencing biologic activity. Due to this fact, there has been a drive toward the development of single enantiomers as new drugs that provides the opportunity to optimise the therapeutic ratio (index). In fact, single enantiomers of existing racemic drugs such as ibuprofen and bupivacaine have been developed as new products. Development of racemic drugs now requires detailed investigations of the pharmacokinetics and biotransformation of the individual enantiomers.

The cardiovascular drug propranolol is used as a racemate (i.e., an equal mixture of two enantiomers), with most of the therapeutic activity mediated by the (–)isomer. One of its major biotransformation pathways in the dog is glucuronidation, and urinary excretion of the glucuronic acid conjugate of (–)propranolol is about fourfold greater than that of the (+)isomer; thus, plasma concentrations of the latter are greater than those of the former. Ring hydroxylation is another important pathway, and for this process in humans, there is a preference for the (+)isomer, leading to greater plasma concentrations of the active (–)isomer.

Some biotransformations introduce an asymmetric center into a drug and these often proceed stereospecifically. The most common examples are hydroxylation of a secondary carbon and the reduction of ketones to secondary alcohols. Ibuprofen undergoes both ω and $\omega-1$ oxidation of the isobutyl side chain, and formation of the resulting carboxylic acid metabolite introduces a second asymmetric center into the molecule. Both ibuprofen enantiomers have been shown to undergo stereospecific oxidation to give a metabolite with the same configuration at the new asymmetric center.

Stereochemical inversion is another aspect of stereospecific biotransformation. The 2-arylpropionic acids containing an asymmetric center represent a major class of the nonsteroidal anti-inflammatory drugs. A notable aspect of their biotransformation is the conversion of one enantiomer to the other. Although most of these drugs were originally developed and used as a racemic mixture, only one of the isomers is usually regarded as being biologically active. The inactive (R) isomer of ibuprofen is converted to the active (S) isomer in vivo. A possible mechanism is dehydration to an α -methylene intermediate; this stage, involving a flavin-dependent dehydrogenase (FAD), is stereospecific (Eq. 34).

FACTORS AFFECTING DRUG BIOTRANSFORMATION

The preceding sections have illustrated that drugs can be biotransformed by a variety of reactions that are generally enzyme catalyzed. The rates of these reactions and their relative importance may be modulated by a number of potential interacting factors that can be broadly classified as physiologic or environmental. The influence of most of the factors mentioned has been revealed by laboratory animal studies, often involving high dose levels and exaggerated systemic exposure. In humans, where a single factor may not be seen to exert any notable effect, the interplay of several factors could contribute to important alterations in drug biotransformation and thereby to drug action.

Physiologic

Age

The activities of the enzymes responsible for drug biotransformation generally seem relatively low in the fetus, then increase rapidly after birth to reach adult levels, and then eventually decline in old age. However, the developmental profiles of the various enzymes probably depend on the species and the enzyme system. The decline of drug biotransformation capability in old age may have important clinical consequences because the elderly comprise much of the patient population, whereas the pharmacokinetics and biotransformation of new drugs are mostly studied and first defined in young, healthy subjects. Similarly, limited drug biotransformation capability in the very young requires careful selection of drug dose regimens in pediatrics.

Disease

In modern drug development, a knowledge of drug biotransformation and pharmacokinetics in certain disease states is essential, especially disease states of the liver and kidney because of their key role in drug elimination from the body. The impairment of these organs by disease could result in altered pharmacokinetics and drug and/or metabolite accumulation in the body. Cardiovascular disease is also of importance because of possible alterations in blood flow that could affect drug transport to the eliminating organs.

Hormones

A deficiency or surfeit of certain hormones can influence the activity of the enzymes involved in drug biotransformation. Apart from the sex hormones, those of the adrenal, pancreas, pituitary, and thyroid also exert effects on the regulation of certain enzyme activities. Some hormonal disease states, such as diabetes and hyperthyroidism, could have important implications for drug biotransformation. Alterations in drug biotransformation can occur in pregnancy, and this subject area requires much more study.

Pharmacogenetics

Intersubject variability in drug biotransformation can be very large primarily due to genetic factors modulated by other factors such as those mentioned elsewhere in this section. Thus the ability of certain individuals to biotransform particular drugs is greatly diminished owing to a genetically inherited deficiency in the enzyme(s) mainly responsible for the biotransformation(s) of those drugs. Although enzyme systems, such as the cytochromes P450 (CYP), have broad and overlapping substrate specificities, one enzyme alone (because of high enzyme-substrate affinity) may be dominant in the biotransformation of a particular drug. Thus a deficiency in this enzyme (or its inhibition by concomitant medication) can lead to exaggerated pharmacologic or toxicologic effects. For example, about 10% of the Caucasian population is deficient in CYP2D6, whereas this deficiency is less than 1% in the Japanese population where the major known CYP deficiency of about 20% is in CYP2C19 (about 5% in Caucasians).

Drugs that have been shown to be subject to pharmacogenetic differences in biotransformation include debrisoquine, perhexiline, phenformin, mephenytoin, tolbutamide, dapsone, isoniazid and sulfadimidine. The

latter three drugs are primarily biotransformed by N-acetylation, a pathway for which about 50% of the United Kingdom population can be classified as slow acetylators and the rest as fast acetylators.

In modern drug development, it is prudent to avoid developing those compounds likely to be exclusively biotransformed by an enzyme known to be deficient in a notable proportion of the population.

Sex (gender)

The biotransformation of certain drugs may differ in males and females. Such sex differences are fairly common in the rat, which is probably the most widely utilized laboratory animal in drug safety evaluation, but have been infrequently reported for humans or even for other laboratory animal species. When encountered, these sex differences appear to arise as a result of the regulation of drug biotransformation by hormones such as growth hormone.

ENVIRONMENTAL

Chemical Exposure

Exposure to chemicals can be intentional or unintentional. The former includes the ingestion of drugs and food additives, alcohol consumption, and tobacco smoking; the latter includes ingestion of agrochemical residues present in food and chemical exposure in the workplace or environment. The extent of exposure may be sufficient to affect the activities of the enzymes involved in drug biotransformation to cause either an increase (induction) or a decrease (inhibition) of these activities. Barbiturates, for example, can cause an increase, and cimetidine can cause a decrease. Induction caused by the organochlorine pesticides DDT and dieldrin and the consequences thereof have been well publicized. The consequences of inhibition of biotransformation are usually more serious than those of induction, and drugs, such as terfenadine and mibefradil, have been withdrawn from clinical use owing to unacceptable drug-drug interactions arising from enzyme inhibition. Paradoxically, others, such as ketoconazole and quinidine, that are potent inhibitors of cytochrome P450 enzymes, remain in clinical use.

Diet

The diet contains an almost infinite number of foreign chemicals, and the enzymes of drug biotransformation

probably evolved to cope with these chemicals. Consequently they were already available to deal with subsequently developed drugs. The activities of these enzymes can be affected by dietary constituents that may serve to increase or decrease them or cause both effects; in alcohol ingestion, enzyme activities show a short-term decrease (inhibition) and then increase (induction). They can also be affected by nutritional status and reflect protein, fat, carbohydrate, mineral, and vitamin intake.

Stress

Stress can perturb the well being of the body and result in alterations in the rate of drug biotransformation. Such stress factors include abnormal temperature, violent exercise, and disease states.

SITES OF DRUG BIOTRANSFORMATION

The liver is usually considered to be the main site of drug biotransformation. Other organs and tissues, including those located at portals of entry or exit of drugs into or from the body, such as the intestinal tract, lungs, skin, and kidneys, also make major contributions. Certain other organs and tissues may be important to the biotransformation of particular drugs; for example, nitroglycerin has been shown to be biotransformed in vascular tissue. Within an individual organ or tissue, the enzyme systems responsible for drug biotransformation are not uniformly distributed but vary in activity according to cell type and differ in subcellular localization. In the lung, for example, cytochrome P450 activity is relatively high in Clara cells.

Although most types of organs and tissues contain the enzyme systems involved in drug biotransformation, the enzyme activities may be expressed by a family of enzymes, whose individual distribution may be either organ or tissue specific. The profile of these enzymes can be altered, for example, during treatment with certain compounds.

The biotransformation of many drugs is often slower in humans than in the laboratory animal species used in drug development and safety evaluation. Lower activities of the respective enzyme systems may be the cause, and indeed the rates of drug biotransformation and the body weights of animal species appear to be correlated to some extent.

IMPACT ON ROUTES OF EXCRETION

The two main routes of systemic excretion of drugs and their metabolites are renal (urinary) and hepatic (biliary). Which of these occurs or predominates depends mainly on the physicochemical properties of the metabolites. Sulfate conjugates are more likely to be present in urine and glucuronic acid conjugates appear more often in bile. Glutathione conjugates are almost exclusively excreted in bile. However, this is both compound- and species-dependent due to molecular-weight thresholds for biliary excretion. Thus, many glucuronides are almost always actively excreted in the bile of rats but excreted primarily in urine of humans and nonhuman primates. Conjugation with sulfate, glucuronic acid, and glutathione increases the molecular-weight by as much as 80, 177, and 307 mass units, respectively. The molecular-weight thresholds for active biliary excretion are about 330 for the rat, and dog; 450 for the rabbit and nonhuman primate; and 500 for humans.

METHODS FOR THE STUDY OF DRUG BIOTRANSFORMATION

In Vivo

Investigations of biotransformation pathways in vivo require the collection and analysis of appropriate biologic samples. The types of sample collected include urine, feces, expired air, blood and/or plasma, bile, milk, saliva, synovial fluid, and tissues. These samples can be divided into two groups: 1) those requiring complete collection (e.g., urine and feces) in order to provide quantitative as well as qualitative information on the excretion of the drug and its metabolites, and 2) those such as blood and milk that are subsampled at specific times to yield information on the identity and time-related concentrations of the drug and its metabolites that contribute to systemic exposure. Samples of the above types can be obtained from all the common laboratory animals used in biomedical research. In addition, with the exception of bile and tissues, similar samples can usually be obtained from humans without great difficulty.

One approach to the identification of metabolites is to investigate the presence of specific compounds in biologic samples when reference compounds are available. Quantitative data will require validated bioanalytic methods for each specific compound and may not be readily obtained from certain biological matrices (e.g.,

feces). In addition, the possible presence of, and interference from, unknown metabolites would frequently create uncertainty.

Another approach is to attempt isolation and identification of all major metabolites, regardless of the availability of reference compounds. This approach requires an unambiguous method of detecting metabolites, such as use of a radiolabeled form of the drug. Provided that the drug is radiolabeled in a metabolically stable position, this approach allows accurate measurement of metabolites in terms of percentage of administered dose and thence in concentration or quantity units. Procedures are well established for the detection and measurement of radiolabeled metabolites after chromatographic separation mainly by high-performance liquid chromatography and thin-layer chromatography.

Although chromatographic comparison with reference compounds may provide reasonable evidence for the identity of metabolites, more rigorous characterization by application of spectroscopic techniques to isolated samples is highly desirable. Isolation and purification of metabolites are an important prelude to successful structural elucidation. The higher the state of chemical purity, the greater the chance of success in identification. Skillful selection of procedures according to the physicochemical properties of the metabolite can greatly facilitate generation of a viable sample. The most common technique for structure elucidation is mass spectrometry due to the very high sensitivity and versatility of this technique for the introduction of samples into the mass spectrometer. Further developments to increase sensitivity and specificity, new ionization techniques, and direct combination with high-performance liquid chromatography are ensuring the prime role of mass spectrometry. Other techniques that complement mass spectrometry are nuclear magnetic resonance spectroscopy (particularly the emerging technique of LC-NMR), that generally requires larger samples of greater purity, and less commonly, infrared and ultraviolet spectroscopy.

In Vitro

Several biologic systems can be utilized for the study of drug biotransformation in vitro. These range in remoteness from the living animal in the following order: perfused organs, tissue slices, isolated cells, subcellular preparations, crude enzyme preparations, and purified enzymes. In complexity, these systems range from the relatively simple to the exceedingly awkward; each system has its advantages and disadvantages, and none is ideal. Undoubtedly the most popular system has

been the subcellular preparation because of its ease of production and convenience of use, and because expensive equipment is not always necessary. Indeed, much of the earlier biotransformation knowledge in the literature has been gleaned from the use of subcellular preparations. However, for a better understanding of catalytic mechanism, substrate specificity, and enzyme kinetics, purified enzymes are necessary. In recent years, the increasing availability of cDNA-expressed human enzymes responsible for drug biotransformation is greatly facilitating drug discovery and development. Several of the human cytochrome P450 enzymes and some others are commercially available in this form. Perfused organs and isolated cells are often regarded as providing a better reflection of what might occur in the intact animal in vivo when the overall biotransformation of a compound is being considered; the latter are the much more popular.

BIOSYNTHESIS OF DRUGS

Geoffrey A. Cordell

Kyung Hee Lee

University of Illinois at Chicago, Chicago, Illinois, U.S.A.

BIOSYNTHESIS AND BIOGENESIS

Metabolism is the series of pathways operating when biological systems synthesize their constituents. *Biosynthesis* is the experimentally established pathway of formation of secondary metabolites; where experimental proof is absent, the term *biogenesis* is used.

SECONDARY METABOLITES

Reaction products that are necessary for the generative functions (respiration and catabolism) of an organism are termed primary metabolites; those resulting in products used for other functions are known as *secondary metabolites*. Such compounds typically characterize the individuality of an organism or a group of organisms; this study is termed chemotaxonomy. Consequently, the biosynthetic pathways of secondary metabolism are not random but are highly conserved. Thus, a given plant family may produce substantial numbers of a certain type of metabolite (e.g., quassinoids in the Simaroubaceae), whereas another family produces quite different metabolites (e.g., monoterpene indole alkaloids in the Apocynaceae).

THE PRECURSORS

A select group of primary metabolites, predominantly acetate, shikimic acid, isopentenyl pyrophosphate, and a few amino acids, is responsible for the diversity of the 135,000 plant-derived secondary metabolites in 12 major classes (Fig. 1). Only those classes with some social or economic significance as bioactive agents are discussed here.

SIGNIFICANCE OF BIOSYNTHESIS

Biosynthetic knowledge is an integral and essential aspect of natural products chemistry and has recently assumed

high-profile academic and commercial significance for biotechnological reasons. It is the foundation permitting a systematic and rational framework for organizing the bewildering structural diversity of mammalian, arthropod, insect, plant, microbial, and marine secondary metabolites. It provides structural clues for new metabolites through biogenetic possibilities based on established biosynthetic schemes. It permits the bioengineering of metabolic pathways for enhanced yields or the altering of desired product profiles for greater economic gain. Manipulations at the genetic level may afford a substantially new array of metabolites for future drug discovery. Finally, it is of fundamental human curiosity to discern how secondary metabolites are produced in living systems. The modification of such processes at the enzyme or gene level may be of critical importance in the treatment of mammalian processes involved in disease states; cholesterol synthesis-inhibiting drugs, such as mevinolin, are an example.

METHODS IN BIOSYNTHESIS

Biogenetic theories arose as the need to classify diverse secondary metabolites became apparent. Biosynthetic experimentation tested hypotheses when the precursors became available in radio-, and subsequently stable, isotope labeled forms. It focuses on the study of precursor relationships (including the stereochemistry of specific processes) and of the enzymes involved in the succinct steps in the pathway. A typical experiment involves the administration of a potential precursor in labeled form to the organism, at a time when it is known that the organism is actively producing the metabolite of interest. After an appropriate period of time, the organism is processed for the metabolite of interest and the isotope content located and measured. Most of the fundamental pathways of natural product biosynthesis were established using the radioactive isotopes of hydrogen and carbon, ^3H and ^{14}C . Extensive use is now made of the stable isotopes of the key atoms present in natural products, ^{13}C , ^{18}O , ^{15}N , and ^2H .

Evaluation of the structural complexity of natural products, coupled with prior biosynthetic knowledge,

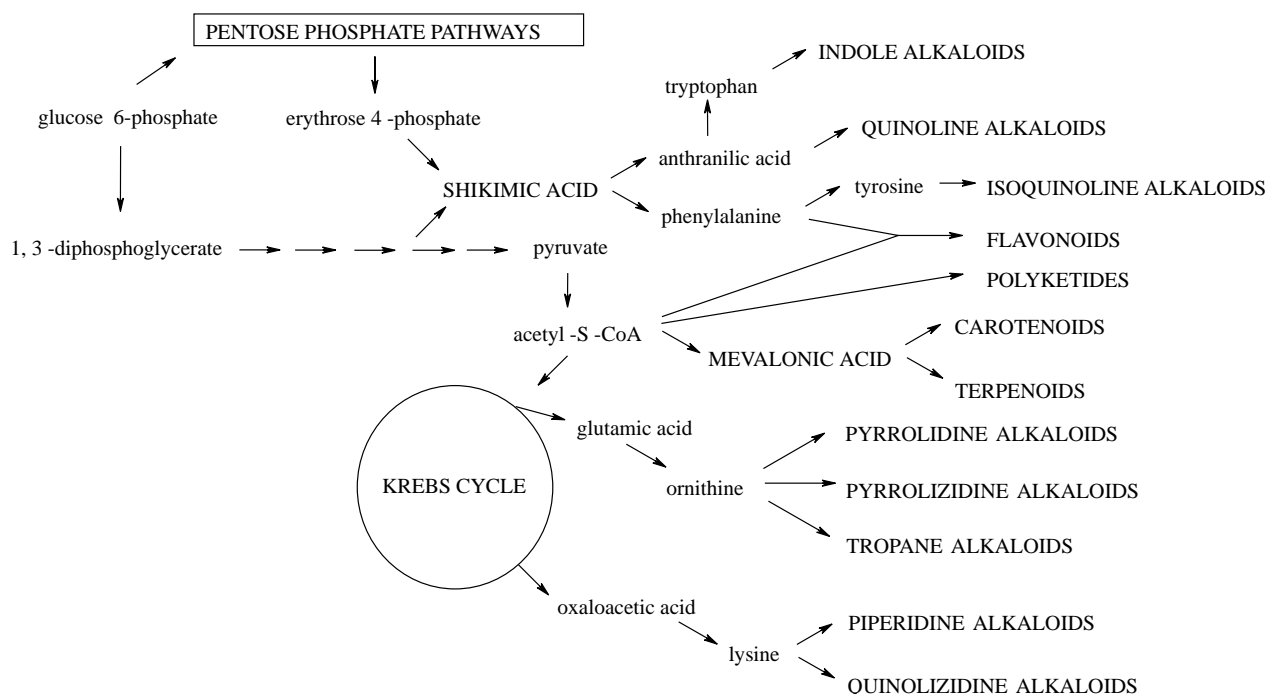

Fig. 1 The biosynthetic origin of secondary metabolites.

frequently offers a rational overview of the necessary chemical transformations. This may lead to isolation of the enzymes and perhaps the involvement of unanticipated intermediates. Although frequently these pathways are conserved, given the diversity of metabolic systems, it should not be assumed that the same compound will be produced by the same biosynthetic pathway in a different organism, i.e., in one plant family compared with another.

For biosynthetic experiments to be meaningful, the precursor must reach the site of synthesis at a time when the enzyme systems mediating metabolite formation are both present and active. Secondary metabolism occurs at a discontinuous rate in a given organism and at different points in the growth cycle in different organisms. Consequently, establishing a time for precursor administration to the organism is critical, if substantial degradation is to be avoided. Transportation and permeability factors may result in very low incorporations, even if the organism is known to be producing secondary metabolites at the time of the feeding and a known precursor is being used. Translocation of the precursor to the site of synthesis may be important in studies with whole plants or callus tissue. For microorganisms, metabolic degradation may occur because the growth of cell mass frequently precedes the initiation of secondary metabolite production.

Use of Radioisotopes

Although a single radiolabel may be adequate to demonstrate a preliminary precursor relationship through incorporation, it is preferable to use a precursor containing two, different, strategically placed labels. There are two types of these experiments, one in which two labeled precursors are physically mixed and the ratio of labels monitored. An example is a feeding experiment with $[2-^{14}\text{C}, 4-^3\text{H}_2]$ -mevalonic acid. A second experiment involves using a precursor in which the two labels are in the same molecule; the use of $[1,2-^{13}\text{C}_2]$ -acetate is an example. Double- or multiple-labeled substrates are used to examine bond-forming and bond-breaking reactions and to examine the stereospecificity of enzymatic processes if the precursor is labeled stereotopically (e.g., $[4R-^3\text{H}]$ -mevalonic acid) and is selectively retained in the product or if the label in the product can be assigned stereotopically. Techniques are available for distinguishing between the prochiral hydrogens on a methylene or a methyl group.

Use and Detection of Stable Isotopes

The common stable isotopes used in biosynthetic studies are ^{13}C , ^2H , ^{15}N , and ^{18}O . Stable isotope-labeled

precursors have replaced radiolabeled precursors in many biosynthetic studies for the following reasons: 1) no appropriate radiolabeled isotope is available (e.g., N and O); 2) the detection methods frequently permit location of the label in the product directly; and 3) radiocontamination and safety issues are reduced. The negative aspects of stable isotope studies are: 1) detection methods are relatively insensitive (higher incorporation levels needed); 2) high levels of enrichment of the label in the precursor are required; and 3) reasonable quantities of the precursor are necessary, which can be expensive.

Mass spectrometry and NMR spectroscopy are the dominant techniques for detecting stable isotopes. MS offers the advantage that less sample is needed to establish incorporation, whereas NMR typically permits direct determination of the labeled site.

Administration of Precursors

When the system under examination is microbial, i.e., a plant in tissue culture or a cell-free system, administration of the precursor is straightforward. For meaningful conclusions, a profile of formation of the compound of interest over time is necessary so that feeding is conducted when there is active product formation. When intact plants are used, precursor feeding is more difficult; options are wick feeding through the stem, root feeding, isolated leaf feeding, or even direct injection into the stem.

Examining Intermediates

Conclusively establishing the role of potential intermediates in a biosynthetic pathway is a difficult aspect of biosynthesis. Typically, intermediates accumulate because subsequent enzymatic reactions are slow. Organisms also produce shunt metabolites that are off the main pathway and may not be further metabolized; these will also accumulate. Isolation of an "intermediate" does not, therefore, establish intermediacy. Trapping experiments are sometimes used to overcome these problems. In the pathway $A \Rightarrow B \Rightarrow C$, where A is a known precursor of C , labeled A and nonlabeled B are fed at the same time. The latter is metabolized to C and labeled B is produced from A ; B is then temporarily available for isolation. An alternative approach for microbial metabolites is to mutate the organism or add specific enzyme inhibitors. This may allow intermediates to accumulate. Incorporation of a labeled, potential intermediate into a product does not prove that the intermediate lies on the main biosynthetic pathway. It may simply serve as a substrate for the enzymes involved. Only when each of the enzymes in a

pathway has been isolated and characterized, and the substrate specificity determined, can the intermediates in a biosynthetic route be characterized.

Enzymes and Genes

Biosynthetic pathways are characteristically under enzymatic control and proceed with a very high degree of stereospecificity. Compared with the number of steps in the pathways of significant natural products, very few enzymes have been isolated and characterized and even fewer cloned and expressed. In the future, it will be very important to be able to express these enzymes heterologously in more productive systems so that these biocatalysts can be used for both known metabolite production and new metabolite generation.

One dream of the biosynthetic chemist is to develop a system of stabilized enzymes on solid supports, permitting a continuous flow process from precursors to products. With no variability due to climate or soil conditions, yields would be totally controllable and reproducible, and product clean-up would be greatly simplified, or ideally, unnecessary. With the isolation, characterization, cloning, and expression of more enzymes in biosynthetic pathways, the reality of the dream moves inexorably closer. Already the use of enzyme systems for directing stereospecific reactions in organic synthesis has risen dramatically, with a corresponding increase in efficiency and enantioselectivity.

Combinatorial Biosynthesis

Another biosynthetic dream is the ability to modulate predictably the product profile of an organism. In the microbial and plant tissue culture areas, this can be achieved randomly by modifying the growth medium or by challenging the organism with a chemical or other external agent (such as a fungus), producing metabolic stress metabolites (allelochemicals). A more controllable route to altering a metabolic profile in the polyketide area can be achieved through selectively modifying the gene sequence of the biosynthetic pathway. Known collectively as combinatorial biosynthesis, this way allows new products to be formed for chemical analysis and biological evaluation.

COMPOUNDS DERIVED FROM ACETATE

Acetyl coenzyme A is the biosynthetically active form of the two-carbon building block, acetate. It is of central

importance in mammalian, plant, and microbial biochemistry, giving rise to the fatty acids, the polyketides, and through mevalonic acid, the terpenes.

Fatty Acid Biosynthesis

The common fatty acids, such as palmitic (C_{16}), stearic (C_{18}), and arachidonic (C_{20}), have an even number of carbons. Their chain building process initially involves a reaction of acetyl CoA with carbon dioxide to afford the more chemically reactive malonyl CoA, which condenses with a second acetate unit. The carbon dioxide subsequently lost is the same carbon that was added. It is this specificity that allows correlative experiments with $[1,2-^{13}C_2]$ -acetate. Reduction of the beta carbonyl group is followed by dehydration and reduction of the *cis*-olefin to the saturated fatty acid. Repetition causes chain extension by two-carbon fragments (Fig. 2). Unsaturated fatty acids can also result from dehydrogenation, as shown in the conversion of oleic acid to arachidonic acid. The latter compound is the precursor of the prostaglandins (Fig. 3). Branching in fatty acids may occur either through the initiating acid, through acylation with a preformed fatty acid, or through reaction of an intermediate olefin with methionine.

The Polyketide Pathway

Aromatic compounds are predominantly formed through either the shikimate (vide infra) or the polyketide pathway. Collie first suggested the polyketide pathway in 1893, and this was extended theoretically (acetate hypothesis) and experimentally by Birch. Factors involved in the diversity of products include the chain-initiating unit, the number of units in the cyclizing chain, condensation reactions occurring between separately formed polyketide chains,

Fig. 2 The biosynthesis of fatty acids.

Fig. 3 The biosynthesis of prostaglandins.

and secondary processes, such as alkylation or halogenation. The 1,3-diketone nature of the intermediate chain leads to a characteristic *meta*-relationship between ether or phenolic groups; in shikimate-derived metabolites these groups are typically *ortho*-related.

Penicillic acid provides an example of a simple tetraketide whose aromatic ring is cleaved and cyclized, as shown by experiments with $[1,2-^{13}C_2]$ -acetate (Fig. 4). On the other hand, the pentaketide citrinin is the result of the cyclization of a linear polyketide chain wherein three methyl groups are introduced from methionine (Fig. 5). Hexaketide derivatives are rare. The naphthoquinone plumbagin is an example where cyclization followed by decarboxylation occurs. Griseofulvin is a heptaketide (Fig. 6) and was one of Birch's very early demonstrations of the accuracy of the acetate hypothesis. Anthraquinones, such as islandicin, are octaketide derivatives; the two alternative modes of cyclization of the polyketide chain

Fig. 4 The biosynthesis of penicillic acid.

Fig. 5 The biosynthesis of citrinin.

Fig. 6 The biosynthesis of griseofulvin.

can be distinguished through the use of $[1,2-^{13}\text{C}_2]$ -acetate. Xanthenes can be produced through oxidative cleavage of the quinone ring, cyclization and decarboxylation (Fig. 7).

The most clinically significant polyketides are the anthracycline and tetracycline antibiotics produced in *Streptomyces* cultures. The tetracyclines demonstrate that chain initiation can occur with a malonamide unit and that a wide range of reactions can occur after the initial aromatic cyclization (Fig. 8). Mixed biosynthesis is very evident in the macrolide antibiotics, where various combinations of acetate and propionate form the chain (e.g., tylosin and nystatin) or only propionate (e.g., erythromycin) and cyclize to a ring of varying size. Several plant-derived anthraquinones are of clinical significance, including the sennosides of senna (*Cassia angustifolia*), the aloins of aloe (*Aloe vera* and related species), the cascarosides of cascara sagrada (*Rhamnus purshiana*), and hypericin of Saint John's Wort (*Hypericum perforatum*; Fig. 9).

SHIKIMATE PATHWAY

The majority of aromatic compounds, including most alkaloids, are derived through the shikimate pathway. At

the branching point of chorismic acid, either anthranilic acid, the precursor of tryptophan, or prephenic acid, the precursor of phenylalanine, itself the precursor of tyrosine and dopa (3,4-dihydroxy-phenylalanine), is formed (Fig. 10). Phosphorylation at the 3-position, condensation with phosphoenolpyruvate, and elimination of phosphoric acid yields chorismate from shikimate. Chorismate is also the precursor of a number of simple, and very important, aromatic compounds, including salicylic acid, 4-amino-benzoic acid (PABA), a constituent of folic acid, and 2,3-dihydroxybenzoic acid, a key acylating group of enterobactin.

Amination at the 2-position and loss of pyruvate yields anthranilic acid, the precursor of the quinoline alkaloids, distributed widely in the Rutaceae, and tryptophan, the precursor of the indole alkaloids (Fig. 10). Internal Claisen rearrangement on chorismic acid yields prephenic acid en route to phenylalanine. During the course of the hydroxylation of phenylalanine to tyrosine, there is a characteristic NIH shift of the proton at C-4' (Fig. 11). Further hydroxylation yields dopa, used in the treatment of Parkinson's disease. Dopa can oxidize and polymerize to yield the melanin group of hair, skin, and eye pigments. 4'-amination of chorismic acid, a Claisen rearrangement, and amination yields 4'-aminophenylalanine, whose importance is as a precursor of chloramphenicol (Fig. 12).

Fig. 7 The biosynthesis of anthraquinones and xanthenes.

Fig. 8 Representative polyketide antibiotics.

Oxidative deamination of phenylalanine by phenylalanine ammonia lyase (PAL) and 4-hydroxylation affords *p*-coumaric acid, whose derivatives are the fundamental building blocks of lignin, as well as the lignans, such as the

potent anticancer agent podophyllotoxin (Fig. 13). The latter is the template for the drugs, teniposide and etoposide.

2'-Hydroxylation of *p*-coumaric acid, followed by photocatalyzed isomerization of the double bond and

Fig. 9 Representative plant-derived anthraquinones.

Fig. 10 The relationships of shikimate-derived compounds.

lactonization, affords 7-hydroxy coumarin (umbelliferone). Prenylation at the 6-position, epoxidation, cyclization, and a retro-aldol reaction afford the furanocoumarins (Fig. 14); some (psoralen, bergapten) are known as photosensitizers and find use in the treatment of vitiligo and psoriasis. Coumarin stimulates the reticulo-endothelial system and served as a model for anticoagulant drugs, such as dicoumarol and warfarin.

Flavonoids are essentially universal plant pigments and exist in at least nine different structure classes, frequently with attached sugar units. They are derived from a mixed acetate-shikimate biosynthesis. 4-Coumaroyl CoA reacts with a triketide unit to afford 4,2',4',6'-tetrahydroxychalcone, which cyclizes to naringenin under the influence of chalcone isomerase. 3-Hydroxylation and dehydrogenation leads to the

Fig. 11 The NIH shift in the 4'-hydroxylation of phenylalanine.

Fig. 16 The biosynthesis of isoflavonoids.

flavanol, kaempferol (Fig. 15), which, along with quercetin (3'-hydroxykaempferol), is widely distributed. There is very substantial interest in the flavonoids present in the diet for their wide range of *in vitro* activities. *Silybum marianum* (milk thistle) is used in Europe as an antihepatotoxic agent for mushroom poisoning, where the active ingredient is silymarin (a mixture of flavanolignans).

Isoflavonoids are of limited distribution (Fabaceae, bean family) and are probably formed through the epoxidation and rearrangement of the enol form of a flavone (e.g., the conversion of naringenin to genistein; Fig. 16). Several isoflavonoids are associated with strong estrogenic activity, and there is interest in their potential in the prevention of hormone-dependent breast cancer. Rotenoids (e.g., rotenone) from *Derris* and *Tephrosia* species are noted for their insecticidal and cytotoxic activity.

COMPOUNDS DERIVED FROM ISOPENTENYL PYROPHOSPHATE

Numerous natural products contain units derived from a terpene precursor. Built up of five carbon "isoprene" units, they are successively known as hemiterpenes (C_5),

monoterpenes (C_{10}), sesquiterpenes (C_{15}), diterpenes (C_{20}), sesterterpenes (C_{25}), triterpenes (C_{30}), and tetraterpenes (C_{40}). Successive units may join through head-to-tail (e.g., farnesol) or tail-to-tail linkages (e.g., squalene). Isopentenyl pyrophosphate (IPP), derived from either mevalonic acid or 1-Deoxyxylulose, is the moiety isomerizing to dimethylallyl pyrophosphate (DMAPP) and is also the chain extending unit. Fig. 17 shows the relationships between these terpenes and how the steroids are derived from a triterpene precursor. The formation and occurrence of these metabolites is widespread, and many derivatives are essential for mammalian functions (e.g., cholesterol, steroid hormones, bile acids, vitamin D, and retinols).

Geraniol is the primordial monoterpene, and its simple derivatives and cyclization products occur in the oils of many plants, used as flavoring and aromatic agents (e.g., caraway, coriander, dill, eucalyptus, lavender, orange, peppermint, rose, and sandalwood), as well as drugs (e.g., camphor, menthol), and insecticides (e.g., pyrethrins). Chain extension leads to farnesol, which can dimerize to squalene or undergo its own molecular modifications to yield the diverse sesquiterpenes. One of these, artemisinin from *Artemisia annua*, is of significance as an antimalarial agent, and another, (–)-gossypol, is a male contraceptive agent (Fig. 18).

Several diterpene derivatives are commercially significant drugs. Forskolin, from the Indian medicinal plant

Fig. 17 The relationships of the isoprene-derived compounds.

Coleus forskohlii, is a potent inhibitor of adenylate cyclase and shows promise for congestive heart failure and bronchial asthma. The ginkgolides, from the leaves of *Ginkgo biloba*, are potent inhibitors of platelet activating factor, and in a specified mixture with associated flavonoids, they improve peripheral and cerebrovascular function, hence, their wide use for senile dementia and memory loss. Taxol, originally isolated from the yew *Taxus brevifolia*, is a potent agent against many forms of cancer, including ovarian and breast cancer. It acts by promoting the assembly of microtubules (compare podophyllotoxin, colchicine, and vincristine). Geranylgeranyl units are also found in the side chains of chlorophyll a and vitamin K₁. Many *Euphorbia* species have a latex containing tiglane esters noted for their powerful skin irritant and cocarcinogenic activity. Derivatives of an

ent-kaurene alcohol (stevioside, rebaudioside) are non-cariogenic sweetening agents.

Through a series of cyclizations, squalene oxide (C_{30}) affords lanosterol in animals and fungi and cycloartenol in plants (Fig. 19). In both instances, the intermediate is a protosteryl cation that can also undergo a series of Wagner-Meerwein rearrangements to afford the cytotoxic cucurbitacins of melons and cucumbers. Squalene oxide in a chair-chair-chair-boat conformation yields the dammar-enyl cation, a parent of numerous triterpene skeleta (e.g., lupane, oleanane, ursane, and taraxerane) contained in the saponins found in many foodstuffs, in soaps, and in several drugs from complementary systems of medicine (e.g., ginseng, liquorice, *Bupleurum*, and horsechestnut).

Steroids are degraded triterpene derivatives, and the different nuclei are classified based on carbon number.

Fig. 18 Representative mono-, sesqui- and diterpene derivatives.

The most significant, from a drug perspective, are the cholane, pregnane, androstane, and estrane systems. When a carbon, such as a methyl group, is lost from the nucleus, the term *nor* is used.

In animals, lanosterol undergoes a series of degradative steps (Fig. 20), whose sequence depends on the organism to afford cholesterol. In photosynthetic organisms, this role is played by cycloartenol where the cyclopropane ring

Fig. 19 The biosynthesis of lanosterol and cycloartenol.

Fig. 20 Steps in the pathway from lanosterol to cholesterol in mammals.

Fig. 21 Representative degraded triterpenes and steroids, and the carotenoids.

is opened. Cholesterol is in almost every animal tissue, and is derived from cattle brains and spinal chords, as well as lanolin from sheep wool. High levels of blood cholesterol are correlated with a high risk of heart disease and atherosclerosis (through deposition of cholesterol and its esters in the artery wall). Thus, an agent that can selectively inhibit an early stage (HMG-CoA reductase) in cholesterol biosynthesis in humans, such as mevinolin (lovastatin), has the effect of reducing serum cholesterol levels.

The steroidal saponins, typically based on a C_{27} sterol nucleus, are distributed in the Dioscoreaceae, the Agavaceae, and the Liliaceae, and have a spiroketal at C-22 (e.g., diosgenin). They are also characterized by numerous sugar units attached at C-3 and sometimes elsewhere. Although not employed as drugs, steroidal saponins are critical for the semisynthesis of important hormones (estrogens, androgens, and progestins) and selected anti-inflammatory agents. An example is the conversion of diosgenin to a dehydropregnenolone acetate for elaboration to the hormones (progesterone, testosterone, androstenedione, and estrone) and the corticosteroids. Microbial transformations are important in several of the reaction sequences. Ginsenosides, the adaptogenic principles of Korean ginseng (*Panax ginseng*), are polysaccharide derivatives of a trihydroxylated (3β , 12β , and $20S$) dammarane nucleus, and sugar variation occurs at C-3 and C-20 (Fig. 21).

Cardiac glycosides, such as those of *Digitalis lanata*, are composed of a polysaccharide unit of three or four sugars, including some 2,6-dideoxyhexoses, linked at C-3 to a modified polyhydroxy ($C-3\beta$, $C-12\beta$, and $C-14\beta$ in the case of digitoxigenin) steroid nucleus. The modification takes place on a 20-keto-pregnane through hydroxylation, the addition of acetate, and cyclization to yield an α,β -unsaturated butyrolactone. Cucurbitacins, withanolides, ecdysones, guggulsterone, limonoids, and quassinoids are also modified triterpene derivatives with potent biological effects, including high cytotoxicity (Fig. 21).

The carotenoids are tetraterpenes and are formed through the tail-to-tail coupling of geranyl pyrophosphate, followed by cyclizations at each terminal (e.g., β -Carotene in carrots). They are widely used as coloring agents for foods, confectionery, and drugs. β -Carotene is under investigation as an antioxidant for the prevention of cancer. Cleavage of β -carotene yields retinol (vitamin A_1 ; Fig. 21). The retinoids are important signalling agents and regulate many aspects of cell differentiation, embryonic development, growth, and vision (rhodopsin is a derivative of 11-*cis*-retinal with the protein opsin).

ALKALOIDS

Alkaloids are nitrogenous secondary metabolites primarily derived from amino acids for both their nitrogen content and a portion of their carbon framework. However, the approximately 27,000 known alkaloids defy a simple definition. Many alkaloids and their derivatives display

Fig. 22 Representative ornithine- and lysine-derived alkaloids.

profound biological effects and are of enormous commercial, pharmaceutical, and social significance. Ornithine, lysine, phenylalanine, and tryptophan are the principal amino acid precursors.

ALKALOIDS DERIVED FROM ORNITHINE AND LYSINE

There are three principal groups of alkaloids derived from ornithine: nicotine, the pyrrolizidines, and the tropanes, all having significant biological effects. From lysine are derived the piperidine alkaloids (e.g., lobeline, an antismoking agent) and the quinolizidine alkaloids, such as sparteine (an oxytocic agent) and cytisine (a teratogenic agent; Fig. 22). Only the alkaloids derived from ornithine will be discussed here.

Two very different taxa, the Asterales (Solanaceae) and Geraniales (Erythroxylaceae), formulate the tropane nucleus through similar, but distinct, pathways. Using [2-¹⁴C]-ornithine in solanaceous plants, the bridgehead carbon C-1 was labeled, precluding an unbound symmetrical intermediate. In *Atropa belladonna*, ornithine is *N*-methylated prior to decarboxylation to *N*-methylputrescine. By contrast, in *Erythroxylum coca*, the bridgehead carbons C-1 and C-5 were equally labeled, suggesting that an unbound putrescine is methylated. Oxidative deamination affords an aldehyde that undergoes Mannich closure to yield *N*-methyl-pyrrolinium; condensation with acetoacetate affords hygrine-1'-carboxylic acid.

Decarboxylation is followed by oxidative cyclization to tropinone, followed by stereospecific reduction to the α -Hydroxy group, which is esterified to hyoscyamine. The esterifying ester, tropic acid, is an intramolecularly rearranged phenyllactic acid (derived from phenylalanine). Further elaboration of hyoscyamine yields scopolamine (Fig. 23). The enzymes for this transformation are known.

In the biosynthesis of cocaine, the carboxylic acid is retained as the methyl ester, and after stereospecific reduction to afford the β -alcohol, benzylation affords cocaine (Fig. 23). Although cocaine is widely recognized as a drug of abuse, for many populations in South America, the chewing of coca leaves is a routine aspect of the working day and has been for thousands of years.

There are no drugs based on the pyrrolizidine alkaloids of the Asteraceae (e.g., *Senecio* and *Symphytum*) and Boraginaceae (*Crotolaria*). However, these alkaloids pose a great threat to human and animal health because of their potential for inadvertent consumption. In the case of 1,2-dehydro derivatives, such as senecionine, ingestion leads to nonreversible hepatotoxicity. Pyrrolizidine nucleus formation from two units of ornithine is shown (Fig. 24).

ALKALOIDS DERIVED FROM PHENYLALANINE AND TYROSINE

The isoquinoline alkaloids are the second largest group of alkaloids, numbering about 6000, and can be viewed as five

Fig. 23 The biosynthesis of the tropane alkaloids.

Fig. 24 The biosynthesis of the pyrrolizidine alkaloids.

Fig. 25 Simple alkaloids derived from phenylalanine and tyrosine.

subgroups—the simple tetrahydroisoquinolines, the benzyloisoquinolines, the phenethylisoquinolines, the Amaryllidaceae alkaloids, and the monoterpene isoquinolines. In addition, there are a number of simple phenethylamine derivatives, including ephedrine (originally from *Ephedra* species, but now synthesized) and pseudoephedrine, used for asthma and nasal decongestion, respectively. Khat (*Catha edulis*) is widely used as a stimulant in the southeastern Arabian peninsula and contains cathinone. Tyrosine is the precursor of the neurotransmitter noradrenaline and the hormone adrenaline. The hallucinogen mescaline, from the mushroom *Lophophora williamsii*, is also a member of this series (Fig. 25).

An aldehyde, 4-hydroxy-phenylacetaldehyde, operating under the influence of the enzyme norcoclaurine synthase, condenses with dopamine to afford (S)-norcoclaurine,

the progenitor of all benzyloisoquinoline alkaloids (Fig. 26). Robinson, in 1917, was the first to suggest the biogenetic derivation of the pavines, aporphines, morphinans, and protoberberines from a benzyloisoquinoline precursor. These ideas led to a correct proposal for the structure of morphine and were expanded to embrace numerous alkaloid classes (Fig. 27).

Papaverine is one of the few commercial alkaloids synthesized, rather than isolated. It is used either alone for various vascular disorders or in combination as an antispasmodic. The several classes of bisbenzyloisoquinoline alkaloid are based on the number of bridges between the units and their orientation. The alkaloids are common in the Menispermaceae and the Ranunculaceae. One member of the series, tubocurarine, is the prototype for several neuromuscular blocking agents; an activity based

Fig. 26 The biosynthesis of (S)-norcoclaurine and (S)-reticuline.

Fig. 27 Biosynthetic interrelationships of the major classes of benzyloquinoline alkaloids.

on the ethnobotanical use of the tube curares (*Chondrodendron* species) is its use as arrow poisons in the upper Amazon.

Phenol oxidative coupling was proposed by Barton and Cohen in 1957 to enumerate the relationships between many of the benzyloquinoline alkaloid groups (Fig. 27) and accounts for the importance of reticuline as a precursor. In the case of berberine, phenolic oxidative coupling occurs between the *ortho* benzylic position and the *N*-methyl carbon (berberine bridge) to afford scoulerine (Fig. 28). Many of the enzymes in this pathway have been elucidated by Zenk and coworkers. The protoberberines themselves are the precursors of several

groups of alkaloids, including the protopines, the benzophenanthridines (e.g., sanguinarine, used as an antiplaque agent) and the phthalideisoquinolines (e.g., β -Hydrastine, a constituent of *Hydrastis canadensis*; Fig. 29). Berberine is a widely used antimicrobial agent, being active against *Staphylococcus*, *Streptococcus*, *Proteus*, *Vibrio*, etc. (Fig. 28).

Morphine and related alkaloids are specific to the genus *Papaver* (Berberidaceae), although the antipodal series of alkaloids is distributed in the Menispermaceae. Early in the biosynthesis of morphine, an inversion at C-1 of (*S*)-reticuline occurs, followed by *ortho*-*para* benzylic coupling to afford salutaridine. Stereospecific

**Fig. 30** The biosynthesis of morphine.**Fig. 31** The biosynthesis of colchicine.

Fig. 32 The biosynthesis of some Amaryllidaceae alkaloids.

reduction and cyclization-elimination affords the 4,5-Ether bridge and thebaine. The dominant pathway from this point involves neopinone, codeinone, codeine, and morphine. Again, most of the enzymes in this sequence were isolated and characterized by Zenk's group (Fig. 30).

Morphine binds with very high affinity to several receptors in the CNS and is a potent analgesic and central depressant. It is also the prototype for many semisynthetic derivatives (e.g., naloxone, oxycodone, ethorphine, nalbuphine, and buprenorphine) with various degrees of analgesic and narcotic properties. Heroin is diacetyl morphine.

Colchicine is a phenethylisoquinoline alkaloid from the autumn crocus, *Colchicum autumnale* (Liliaceae), a plant used since at least the fifth century to treat gout. *Gloriosa superba* (Liliaceae) is an alternative source. Colchicine inhibits microtubule formation at a specific site, and at a dose of 10 mg, it causes fatal respiratory arrest and renal insufficiency. It is used for the prevention and treatment of gout. The biosynthesis remains unclear; autumnaline has been proposed as an intermediate which undergoes *para-para'* coupling to afford *O*-methyl androcymbine. Hydroxylation, cyclopropane ring formation, and ring expansion affords colchicine (Fig. 31).

Fig. 33 The biosynthesis of emetine.

Fig. 34 Simple alkaloids derived from tryptophan.

The Amaryllidaceae alkaloids (e.g., lycorine) are derived from the phenol oxidative coupling of a $\text{C}_6\text{C}_2\text{NC}_6\text{C}_1$ unit. One unit ($\text{C}_6\text{C}_2\text{N}$) is derived from

tyrosine, whereas the other (C_6C_1) is projected to be derived from phenylalanine, followed by oxidative deamination, hydroxylation, and cleavage of a two-carbon

Fig. 35 Representative ergot alkaloids.

Fig. 36 The biosynthesis of the ergot alkaloids.

unit to afford a dihydroxylated benzaldehyde. *Para-ortho'* coupling leads to lycorine, whereas *para-para'* coupling affords galanthamine, of interest as a cholinesterase inhibitor (Fig. 32).

The monoterpene isoquinoline alkaloids are constituents of the genus *Cephaelis* and selected other Rubiaceae

species. *C. ipecacuanha* (ipecac) is a powerful emetic whose active principle is emetine, derived through the condensation of dopamine and secologanin (Fig. 33). Emetine is also a powerful amebicide, antiviral, and inhibitor of protein synthesis. It is now largely replaced by synthetic dehydroemetine.

Fig. 37 The biosynthesis of strictosidine.

Fig. 38 The biosynthesis of ajmaline, ajmalicine, α-yohimbine, reserpine, and rescinnamine.

ALKALOIDS DERIVED FROM TRYPTOPHAN

Numerous clinically important alkaloids are also derived from-tryptophan and are frequently referred to as “indole alkaloids.” They range in molecular complexity from the mammalian hormone serotonin to the complex bisindolic anticancer alkaloid vincristine. In addition, a number of indole alkaloids, particularly those in the carbazole series, are found in peppers (*Murraya* sp.), and simple derivatives of tryptamine (e.g., *N,N*-dimethyl-5-methoxy-tryptamine and psilocybin) are found in several sources (e.g., snuffs, mushrooms, and toad skins) with attributed hallucinogenic properties.

Physostigmine, under investigation for potential use in Alzheimer’s disease, is possibly formed from *N_b*-methyltryptamine through a radical mechanism involving C-3 methylation and concomitant C-2 cyclization, followed by *N_b*-methylation (Fig. 34).

The powerful biological effects of ergot have been known for over 1000 years. Ergot is a fungus (*Claviceps purpurea* and species) that grows parasitically on rye and some other grains, and it produces three types of ergot alkaloids—the clavines, the simple lysergic acid-derived, and the peptide lysergic acid-derived alkaloids. The

alkaloids find therapeutic use as agents for postpartum hemorrhage (methylergonovine) and as vasoconstrictors and vasoregulators (ergotamine and 9,10-dihydroergotamine) for migraine headaches. More elaborate synthetic derivatives are also available, including lisuride (for Parkinsonism) and 2-bromo-α-ergocryptine (for prolactin-secreting adenomas and Parkinsonism; Fig. 35).

The biosynthetic pathway to the ergoline nucleus proceeds through 4-dimethylallyl tryptophan (4-DMAT), chanoclavine-I, agroclavine, and lysergic acid. Two *cis*, *trans* isomerizations occur: one before chanoclavine-I and the other before agroclavine, as shown by experiments with [2-¹⁴C]-mevalonic acid and [Z-CH₃]-4-DMAT (Fig. 36). The peptide unit is derived from a combination of three amino acids, one of which is always proline. Several genera in the plant family Convolvulaceae (*Rivea*, *Ipomoea*, etc.) also produce ergot alkaloids.

The largest group of alkaloids is the monoterpene indole alkaloids, distributed in the Apocynaceae (mutual exclusion with cardenolides) and in the Rubiaceae and Loganiaceae. The molecular acrobatics of the various systems derived from deglycosylation of the primordial alkaloid strictosidine accounts for this stunning structural diversity.

Fig. 39 The biosynthesis of vinblastine.

Strictosidine is produced, stereospecifically, from tryptamine and secologanin by strictosidine synthase, isolated from several species producing monoterpene indole alkaloids. The enzyme was cloned and can be expressed in large quantity (Fig. 37).

After deglycosylation, the pathway proceeds through a 4,21-Dehydrogeissoschizine derivative to ajmalicine (an α -Blocking spasmolytic agent, used for tinnitus and cranial trauma with an ergot derivative). If cyclization occurs between C-17 and C-18, the yohimbine nucleus is

produced, whose derivatives include the *Rauvolfia* alkaloids reserpine and rescinnamine (antihypertensive activity). Ajmaline, formerly used as an antiarrhythmic, also occurs in *Rauvolfia* species, and several of the enzymes in the pathway have been isolated. Recent considerations suggest that the C-16–C-5 bond may be formed before the N-4–C-21 bond (Fig. 38).

The subsequent steps from geissoschizine to form the *Strychnos* alkaloids, the secodines, the *Aspidosperma* alkaloids and the iboga alkaloids remain speculative, based

**Fig. 40** Representative advanced indole alkaloids.**Fig. 41** The biosynthesis of camptothecin.

Fig. 42 The biosynthesis of quinine and quinidine.

on low levels of incorporation of early precursors or alkaloid time course studies. Joining C-2 and C-16 while moving C-3 to C-7, yields the strychnan skeleton of strychnine (lethal dose 0.2 mg/kg), still used as a rodenticide in some countries.

If the C-15,C-16 bond is oxidatively cleaved, the secodine skeleton results (the proposed progenitor of the

Aspidosperma and the iboga systems) through alternative Diels–Alder type cyclizations to afford tabersonine and catharanthine. The bisindole alkaloids of *Catharanthus roseus* reflect the union of vindoline and catharanthine to afford anhydrovinblastine; modification affords the clinically significant alkaloids, vinblastine (VLB) and vincristine (VCR; Fig. 39). The alkaloids, particularly VCR, are important as anticancer agents and have led to the development of the semisynthetic derivatives vindesine and vinorelbine (Fig. 40). Synthetic approaches are available to join the monomeric precursors. The enzymatically controlled sequence of reactions from tabersonine to vindoline has been elucidated.

Through a biomimetic approach, tabersonine is also the semisynthetic precursor of vincamine, a Eburna alkaloid isolated from *Vinca minor*, and is used for cerebral insufficiency in Europe. *Tabernanthe iboga* has a long history of use as a stimulant in tropical Africa; its main active principle is ibogaine, a controlled substance in many countries (Fig. 40). It is being actively investigated in the United States for its potential to induce opium addiction withdrawal.

Camptothecin, a quinoline alkaloid from *Camptotheca acuminata* (Nyssaceae), is derived from strictosidine through strictosamide (Fig. 41). Originally isolated in 1966, it biologically inhibits topoisomerase I, and in 1996, two derivatives, topotecan and irinotecan, were approved for the treatment of ovarian cancer and

Fig. 43 The biogenesis of aconitine.

Fig. 44 Representative steroid alkaloids.

colon cancer, respectively. Other derivatives are in clinical trial.

Cinchona species (Rubiaceae) are sources of quinine and quinidine, containing a quinoline nucleus and derived through the extensive elaboration of strictosidine (Fig. 42). The intriguing history of the antimalarial quinine and its role in world politics over the past 350 years are legendary. It is frequently the only antimalarial drug to which patients are not resistant. Its widest use, however, is in the beverage industry in tonic water. Quinidine, an isomer of quinine, is used to treat cardiac arrhythmias.

ALKALOIDS BASED ON A TERPENE SKELETON

Although a variety of monoterpene alkaloids and some sesquiterpene alkaloids are known, they are of little

biological interest. By contrast, the diterpene alkaloids of the Ranunculaceae, for example from *Aconitum* and *Delphinium* species, have profound biological effects. The principal alkaloids of interest are those related to aconitine, acting by exciting and paralyzing peripheral nerve endings. The plants are some of the most toxic known, with merely 10 g of aconite root being lethal. Detoxified root preparations are used as drugs in several major systems of traditional medicine. Formation of the aconitine nucleus is thought to occur through a rearrangement of the kaurane skeleton (Fig. 43).

The steroidal alkaloids have a nucleus based on 21, 24, or 27 carbon atoms (Fig. 44). The C_{21} alkaloids are pregnane-derived with nitrogen inserted at C-3, at C-20, or at both positions. They are characteristic of the Apocynaceae (*Funtumia* and *Holarrhena* species) and the Buxaceae (*Buxus* species). The Buxaceae also produces C_{24} alkaloids based on the cycloartane skeleton.

Fig. 45 The biosynthesis of purine alkaloids.

Fig. 46 Some alkaloids derived from acetate and histidine.

Fig. 47 The biosynthesis of penicillin G.

The most interesting alkaloids are those in the Solanaceae and the Liliaceae. These are C_{27} alkaloids, and examples include solasodine and solanidine; many derivatives are glycosylated. The alkaloids from the Liliaceae, such as veratramine of the white hellebore (*Veratrum album*),

were formerly used for cardiac insufficiency. Other alkaloids, for example cyclopamine, are potent teratogens. Biogenetically, they are derived through nitrogen insertion at C-22, followed by a rearrangement generating a C-*nor*-D-*homo* steroid nucleus (Fig. 44). They are not used

Fig. 48 The biosynthesis of desacetylcephalosporin C.

Fig. 49 The biogenesis of nocardicin A.

therapeutically, but the glycoalkaloids of *Solanum tuberosum* (potato) are very toxic and are not destroyed in cooking.

ALKALOIDS DERIVED FROM A NUCLEOTIDE PRECURSOR

Caffeine is one of most widely consumed alkaloids on a daily basis. As well as being a significant constituent of coffee (*Coffea arabica*) and tea (*Camellia sinensis*), caffeine is also present in kola (*Kola* species), guarana (*Paullinia cupana*), and maté (*Ilex paraguariensis*). All of these species are used in various parts of the world to produce beverages that reduce fatigue.

Although some steps remain to be fully elucidated, caffeine is probably derived through a pathway beginning with inosine 5'-monophosphate and proceeds through xanthosine, 7-methylxanthosine, 7-methylxanthine, 3,7-dimethylxanthine (theobromine) to caffeine (Fig. 45). The final methyltransferase has been characterized in coffee and tea, whereas the methylation of xanthosine has only been studied in tea.

Caffeine is noted for its ability to stimulate the CNS and also has positive inotropic and mild diuretic activity. Theophylline (1,7-Dimethylxanthine) is noted for its smooth muscle relaxant activity and its use for chronic asthma.

ALKALOIDS DERIVED FROM OTHER PRECURSORS

Acetate is also a precursor of several groups of alkaloids in the form of a polyketide chain that interacts with an

unknown nitrogen source (as in the terpene alkaloids). Examples of acetate-derived alkaloids are coniine—the toxic principle of *Conium maculatum*, pinidine—from several *Pinus* species, and the naphthylisoquinoline alkaloids (e.g., ancistrocladine)—showing antimalarial and anti-HIV activity. The latter alkaloids are apparently derived from the oxidative coupling of two pentaketide units. Huperzine A, currently in clinical trials for the treatment of Alzheimer's disease and isolated from the club moss (*Serrata huperzia*), is derived from a polyacetate precursor (Fig. 46).

Histidine is a precursor of a very limited number of alkaloids. The most well-known is pilocarpine from *Pilocarpus jaborandi*. The plant was formerly used as a truth serum (diaphoretic activity), and the alkaloid is used to counter the mydriatic effects of atropine.

The penicillins, from the fungus *Penicillium chrysogenum*, are the oldest and most widely used antibiotics. They are formed through stepwise build-up from a tripeptide (ACV) derived from α -Amino adipic acid, cysteine, and valine. Successive oxidation steps form the β -lactam and close the thiazolidine ring to form isopenicillin N. Action of an acyltransferase then yields penicillin G (Fig. 47). Alternatively, hydrolysis of isopenicillin N (or penicillin G) yields 6-aminopenicillanic acid, a key precursor for the wide range of semisynthetic penicillins used therapeutically.

Cephalosporins are modified penicillin derivatives produced by *Cephalosporium acremonium*, wherein isomerization occurs to afford penicillin N followed by a ring expansion involving one of the methyl groups and hydroxylation to produce descetylcephalosporin C (Fig. 48). Once again, removal of the acylating side chain to afford 7-Aminocephalosporanic acid was the key to generating the diversity of available cephalosporin derivatives. The monobactams, such as SQ26,180 from *Chromobacterium violaceum*, contain a 3-Methoxy group

and an *N*-Sulphonate moiety. The carbon framework is derived from serine. More complex derivatives, such as nocardicin A, are formed through a tripeptide pathway similarly to the penicillins (Fig. 49).

BIOTECHNOLOGY AND BIOLOGICAL PREPARATIONS

Ronald P. Evens

Clinical Research, Amgen Inc., Thousand Oaks, California, U.S.A.

INTRODUCTION

A scientific revolution in drug discovery and development occurred in the last 2–3 decades of the 20th century with the advent and full realization of biotechnology. This new discipline resulted in the discovery, development, production, and commercialization of over 60 innovative biological products from 1982 to 1999 that treat over 50 human disease conditions, many of which were major medical breakthroughs. Biotechnology is the use of a living system(s) to discover and produce a pharmaceutical product, often called a biological product because of its structural and biologic similarity to naturally occurring substances in the human body. Biological products have been predominantly proteins, but new biologicals have expanded to include DNA/RNA derivatives, such as m-RNA analogues and genes, peptides, cell therapies, and biologic carriers, such as liposomes. Biotechnology further encompasses biological products that have agricultural uses and environmental applications.

Biotechnology is a collection of biologic techniques and drug development technologies that permit whole new biologic discoveries and products. The techniques and technologies include recombinant DNA (r-DNA) technology, monoclonal antibodies (Mab), antisense, genomics, polymerase chain reactions (PCR), combinatorial chemistry, high throughput screening (HTS), transgenics, proteomics, X-ray crystallography, cell therapy, and gene therapy. These technologies help to elucidate new biologic mechanisms of disease, identify naturally occurring substances responsible for a biologic effect, create duplicates of the natural substances that often are found only in minute amounts in the body, determine new products to enhance natural products or block their functions, and permit mass production of these rare products for commercialization. Fig. 1 displays these technologies, along with traditional drug development techniques (i.e., medicinal chemistry, pharmacology, pharmaceuticals, toxicology, and pharmacokinetics) and good clinical (research) and manufacturing practices, all of which are collectively employed to discover, develop, and produce biological products. More than 60 biological products comprise a new “biological” method to treat human

disease, that is, biotherapy, a new armamentarium for health care providers, to be used in conjunction with drugs, devices, radiology, physical therapy, and psychotherapy.

HISTORY OF BIOTECHNOLOGY

Some science historians will cite that the origins of biotechnology go back 6000–8000 years to the Sumerian culture. Fermentation is an age-old, basic biologic process whereby a living organism, a yeast, will react with carbohydrate materials, such as wheat, in a vessel to produce alcohol. This Sumerian product was beer. Later, this basic biotechnology process (fermentation) was employed in the preparation of bread and cheese, food staples, over the millennia.

The modern era of biotechnology is thought to have started in the 1950s with the discovery by Watson and Crick of the DNA double helix—the matched pairs of four nucleic acids in a specific sequence and in a 3D spatial configuration. Several key discoveries in biology in the 1960s underpin biotechnology; namely, the genetic code is universal in nature among all living things; for the 20 amino acids, 64 specific nucleic acid triplet codes are responsible for interpretation of genes into proteins; and genetic material is transferable among different organisms.

The early 1970s saw the development of the two core technologies of biotechnology, that is, r-DNA and Mab, which account for 48 of the 61 commercially available products in 2000. This DNA process is sometimes called genetic engineering. The r-DNA technology is a process whereby human DNA (genes) is identified, a human gene is inserted into bacterial DNA (plasmid), and the plasmid is placed into the nonhuman host cells (e.g., *E. Coli* bacteria), which manufacture their typical variety of proteins, plus produce a human protein from the human gene. Monoclonal antibodies are proteins that are produced by the body's plasma cells in response to foreign substances, and Mabs serve to attach to and neutralize the foreign substance. A series of discoveries have enhanced the r-DNA and Mab processes including PCR; where genetic material can be accessed and reproduced even a millionfold; sophisticated analytical processes for genes

and proteins; and accelerated gene sequencing techniques. The first commercial product derived from biotechnology was recombinant human insulin.

DRUG DEVELOPMENT TECHNOLOGIES

The products produced through biotechnology, also called biological products, have been primarily proteins, which have been isolated from the human body or created ex vivo to interact with human physiologic systems. About 50 of the 60 commercially available products are proteins. Proteins are complex, large molecules with several key structural features required for their activity. Each protein has a specific amino acid sequence, from the 20 amino acids in nature, which must be preserved intact. Special structural features include disulfide bridges, specific terminal amino acid species, glycosylation (carbohydrate species attached to the protein backbone), and 3D configurations.

Recombinant DNA Technology

The predominant technology in biotechnology during the 1980s and 1990s was r-DNA technology, which was the process used to create more than 35 products, that is, about

60% of the commercially available products. Five steps comprise r-DNA technology: protein identification, gene isolation, cloning and expression, manufacturing (scaleup processes), and quality assurance for protein and process integrity (Table 1). Step 1 involves finding a protein responsible for some biological effect in the human body that has therapeutic potential. The protein needs to be isolated from its normal milieu, usually a body fluid or cell. The structure of the protein is determined, including amino acid sequence, glycosylation (carbohydrate content), disulfide bridging, and possibly 3D configuration. Step 2 requires the isolation of the human gene responsible for the protein, which entails one of three mechanisms. First, if we know the protein's full amino acid sequence, and we do know the 64 nucleic acid triplets that code for the 20 amino acids, we can construct many combinations of those triplet codes that may be genetic representations of the target protein. These genetic constructs are genes, one of which will be identified through screening as the correct gene with the capacity to produce the target protein. Second, we may be able to find the human cell that produces our target protein. In this cell, we can ferret out the messenger RNA (m-RNA) that is responsible through

Table 1 Recombinant DNA technology

Step 1	Protein identification Protein isolation Biological property description Protein sequencing and mapping
Step 2	Gene isolation Nucleic acid triplet sequencing for amino acid sequence mRNA isolation, with reverse transcriptase and complementary DNA DNA probes for genetic library
Step 3	Cloning and expression Gene (human) insertion into plasmids Plasmid incorporation into host cells Host cell production of proteins Master working cell bank
Step 4	Manufacturing scale-up Inoculum stage Fermentation or cell culture stage Protein purification stage Formulation stage
Step 5	Quality assurance Genetic testing Bulk product testing Process validation Final product testing

the process of translation for producing the target protein. The viral enzyme, reverse transcriptase, is capable of creating the target complementary DNA, or gene, from this specific m-RNA. This method was used to find the gene for insulin, which led to marketed products. Third, the human gene could be fished out of the human genome using nucleic acid probes, which is a complex, daunting task. In this method, we identify several peptides in the amino acid sequence of the protein. Using the triplet codes for amino acids, we build a specific nucleic acid combination (probe) for each peptide. Then, we break the chromosomes (3–4 billion pairs of nucleic acids) into thousands of pieces of DNA. Through many, many serial experiments, we try to match the first nucleic acid probe to the DNA mixture, which does create a subset of DNA pieces (hundreds or thousands). In another series of experiments, a second, different nucleic acid probe for a different peptide is matched against this DNA subset for matches. Matches do occur, resulting in a series of possible genes. Each gene must be evaluated by genetics to produce proteins, which then are tested to be sure that the protein has the structural features and pharmacological properties in test animals of the targeted, naturally occurring protein.

Step 3 in r-DNA technology involves cloning of the gene and expression of the protein by the gene. Cloning is the reproduction of the target human gene in a nonhuman cell. Expression is the production of the target human protein by a nonhuman cell containing the human gene. These processes require a vector for the DNA (genes) so that the gene can be carried from cell to cell. A bacterial plasmid is a circular piece of DNA that is transferable between cells (a carrier), will accept the insertion of a human gene, and will allow the human gene to be turned on. The plasmid must be cut open to accept the human DNA (gene) by unique enzymes (restriction endonucleases), each of which is highly specific to a certain nucleic acid sequence that can match a terminal end of the human gene. These “sticky” ends of the opened bacterial plasmid and the human gene permit recombination of the DNA, under the influence of a ligase enzyme, resulting in an r-DNA molecule containing a human gene inserted into a bacterial plasmid. Next, the r-DNA molecule is inserted into a host cell that serves to produce all of its routine proteins, plus the cell manufactures the human protein from the human gene that it carries. The host cell needs to possess several important characteristics: a short reproductive life cycle, a long-term viability in an *in vitro* setting, the ability to accept bacterial plasmids, a good productive capacity for proteins, and the ability to produce the human protein consistently without its alteration. This unique new cell and its offspring, created in the laboratory, are called the master working cell bank.

Step 4 in r-DNA technology is scale-up manufacturing and is comprised of four phases: inoculum, fermentation, purification, and formulation. Inoculum phase entails the use of daughter cells from the new host cell (master working cell bank), actually removed from storage in a -70°C freezer. The daughter cells are grown in a specific medium in serially larger flasks and assessed for normal growth characteristics. The growth medium is a unique and specific mixture of minerals and compounds to enhance cell viability (lifespan) *in vitro* and functional ability of cells to produce proteins. The fermentation or cell culture phase involves inoculating thousand of containers, or large fermenters, with cells from the inoculum phase and adding the growth media. The host cells will proceed to produce proteins, either intracellularly in storage vacuoles for bacterial host cells or extracellularly for mammalian cells. Purification of the protein follows, which varies between bacterial vs. mammalian systems. For bacteria, the cells are removed from the fermenters in a cell paste, which is centrifuged to obtain proteins out of the cells. The protein mixture is then run through an extraction process, often high-pressure liquid chromatography to separate the target protein from all other proteins. For mammalian cells, the culture media containing proteins is collected periodically and replenished. Extraction is basically the same process. A pure bulk protein is the result of purification. The final phase is formulation, wherein a diluent is chosen for the protein, incorporating the best mix of fluids, stabilizers, and minerals to achieve optimal protein stability and maximal shelf life. Formulation of proteins is confounded by the general delicate nature of proteins and the many degrading processes that can occur with them. Most vials of biological products that are proteins do not contain preservatives because of their reactivity with proteins. As can be readily observed from this description of manufacturing r-DNA biotechnology, manufacturing is quite multi-faceted and complex.

Step 5 in r-DNA technology is quality control for the final product, components, and processes throughout the manufacturing process. Proteins are quite complex molecules and their manufacturing is very complex, both of which create high potential for degradation, alteration, or contamination. Protein breakdown can occur through many processes, many of which are listed in Table 2. Contamination can result from typical methods for drugs, e.g., microbial or chemical means, and because of the genetic material employed, through oncogenic or viral DNA incorporation or alteration. Therefore, quality control ensures final product integrity through an extensive series of tests, which involve four key areas: genetic material (plasmids and genes), bulk protein product, final

product, and the manufacturing process. Exemplary tests are listed in Table 3.

Monoclonal Antibody Production

Mabs are complex proteins that have a uniform basic structure, comprised of four subunits that are divided into two matched pairs of protein material—heavy chains and light chains. These Mabs are highly specific proteins that the plasma cells in the human produce against a single antigenic foreign material. Historically, Mabs are produced in biotechnology in a mouse, and are targeted against human antigens. We are developing a product (Mab) to attack and eliminate these target antigens. The mouse will create highly specific Mabs against the human antigen (target); however, the quantity of Mabs (protein) produced by even very large numbers of mice is very small. Hence, biotechnology for Mabs uses a myeloma cell and fuses it with the mouse plasma cell to create a murine hydridoma cell. Myeloma cells impart several additional characteristics to the hybridoma, that is, very high production of proteins (Mabs) and long lifespan, which make Mab manufacturing commercially feasible. These hydridoma cells are the new master cells to produce large amounts of specifically targeted Mabs. The murine origin of Mabs creates significant limits for these products, because administration of murine Mabs to humans leads to the body’s rejection against the murine nature of the protein. Two limits of murine Mabs are a toxic Human Antibody Mouse Antigen response with fever and chills and less binding of the Mabs to the target cell, thus limiting their activity. Therefore, scientists now manipulate Mabs by substituting human subunits for the four murine subunits, creating chimeric molecules, part murine and part human.

Table 3 Quality control tests in r-DNA technology

1. Genetic material (5–10 tests)	Karyotypic analysis
	Oncogene screening
	Gene stability
	Infection DNA screens
2. Bulk protein products (20 tests)	Amino acid sequence
	Peptide maps
	High-pressure liquid chromatography
	Radio immunoassay
	Western blot chromatography
	Bio assay
3. Process validation (10 tests)	Protein yield
	Protein challenge
	Endotoxin spiking
4. Final product (30 tests)	Protein analyses (repeat of #2 above)
	DNA contamination
	Stability tests
	Freeze-thaw tests

This humanization lessens toxicity and could increase activity. We now have eight Mabs available to treat inflammatory conditions or bind to proteins to arrest a process, as in slowing kidney rejection in transplant patients.

Genetic Technologies

In drug discovery and development, genetic materials (DNA, m-RNA, genes, and RNA enzymes) have come to the forefront as biological products and, more so, as primary tools of product discovery. Three primary areas are covered here: antisense, gene therapy, and genomics. Antisense is a RNA molecule that is complementary to, or a mirror image of, a segment of an aberrant or mutated m-RNA molecule, involved in the pathogenesis of a disease. The antisense RNA molecule will bind to the noxious m-RNA molecule, preventing the disease from manifesting. One product is currently available, fornivirsen, used to treat cytomegalovirus associated with retinitis that can occur in AIDS patients.

Gene therapy is a technology employing a gene as a therapeutic agent to treat a disease. The potential goals of gene therapy include replacement of an inactive gene, reactivating inactive genes, turning off genes causing disease, as in oncogenes, turning on further naturally protective genes, or adding a gene characteristic to cells, such as increased susceptibility of cancer cells to chemotherapy drugs. Development challenges in gene

therapy include finding the target gene that is causing the disease or needing enhancements, identifying the optimal target human cell for insertion of an additional gene, insertion (delivery) of an extra gene reliably into a cell, and causing the gene to be functional in a reasonably physiologic manner (extent and duration of activity). We are rapidly isolating and identifying all the genes in the human genome; however, gene delivery has not been achieved in a reliable, reproducible manner sufficient for routine therapy.

Genomics is a technology in which we search for a gene that is responsible for some process or product in the human body. The gene may lead to a new process or disease target for which drugs or biologicals could be developed to favorably alter. For example, the gene for cell immortality was discovered that led to the protein, telomerase, an enzyme. Telomerase is responsible for adding telomeres, short nucleic acid sequences, to the end of all chromosomes, protecting chromosomes from mutations and, ultimately, cell death. Alternatively, genomics may lead to a gene that produces a protein that can be used as a therapeutic agent. For example, osteoprotegerin is a key protein that is the natural substance that turns off osteoclasts, which break down bones and could lead to osteoporosis. Genomics requires the collection of massive amounts of information regarding the human genome or genetics, including protein and peptides, receptors for activity of proteins or drugs, mechanisms of drug activity, and subunits of drugs, proteins, RNA, or DNA responsible for physiologic or pharmacologic actions. The science of informatics now exists to share, integrate, and manipulate these massive amounts of data to create new products.

BIOLOGICAL PROCESSES

Polymerase Chain Reaction

PCR is a critical core process in biotechnology that permits the expansion of the amount of genetic material, starting from minute amounts. The process involves first denaturing DNA with high heat, that is, unraveling the DNA double helix so that the genetic code (sequence) can be read and possibly duplicated. Second, a leader sequence for DNA is used to initiate reading of the genetic code at a specific point, and both helixes or strands of DNA can be read. Third, the enzyme, DNA polymerase, catalyses the reading of the genetic code. By sequential repetition of these three steps, the genetic material is magnified; for example, 20

replications yield a millionfold increase in the DNA material.

High Throughput Screening

HTS is intended to obtain faster more high-quality product leads from large volumes of genetic or peptide molecules. HTS has improved the number of molecules that can be screened for activity by 10- to 1,000-fold. The process of HTS is dependent on improved analytical processes, miniaturization of equipment, and automation. Currently, over 100,000 samples can be tested in a day.

Combinatorial Chemistry

Combinatorial chemistry involves the use of the basic building blocks, either the 20 amino acids or 4 nucleic acids, to build new molecules. All of the different combinations of a set number of building blocks are created; for example, 10 amino acids can result in over 3.5 million compounds. Huge libraries of compounds are produced, which require screening through HTS and the use of informatics to help sort out the structures and actions of all these new compounds.

Cell Therapy

A newer technique to treat disease is based on obtaining healthy cells from a specific tissue, selecting out a specific subset of cells with certain desirable properties, and enhancing the activity of these cells through ex vivo manipulation. We then return these specifically selected, enhanced, and activated cells to patients whose cells are not sufficiently functional, thereby ameliorating a disease. Currently, chondrocytes responsible for cartilage production are taken from a patient's knee that has serious damage and is repairing poorly. These chondrocytes are manipulated ex vivo and returned to the patient to normalize cartilage production. Bone marrow progenitor cells are collected from peripheral blood, bone marrow cells, or cord blood, and the cells with greatest regenerative potential are selected out through various cell-tagging processes. Following life-threatening chemotherapy in a cancer patient that destroys almost all bone marrow, these selected progenitor cells are administered to the patient to accelerate regeneration of bone marrow and white blood cell production, thereby preventing infections. Foreskins of newborns are collected and placed in a 3D construct that permits growth of dermis and epidermis. This construct is used later in venous leg ulcers to accelerate wound healing, thereby reducing healthcare needs.

Molecular Manipulation of Biologicals

A new generation of biological products are derivatives of existing molecules, which are altered to change their properties resulting in new molecules. Pegylation is a process in which polyethylene glycol (PEG) is added to the protein structure, which is being done for alfa-interferon. The addition of PEG may extend the product's half-life or duration of effect, yet the desired activity of the molecule can be maintained.

Glycosylation entails adding carbohydrate species, e.g., sialic acid residues, to the amino acid backbone of a protein. The altered structure in some proteins, such as epoetin alfa, can extend the product's half-life while sustaining its pharmacologic properties.

through r-DNA technology into 11 products (see Table 4). Insulin was the first product from biotechnology to be approved in 1982, and two products are now available. One parent molecule can result in more than one product, because manipulations of the molecule can be done (for example shifting terminal amino acids), without altering the biological activity of the protein. Each molecule may have a related but different indication. Seven growth hormone products are on the market. The generic names of products often will be different from similar products produced by other companies, e.g., follitropin beta from Organon and Follitropin alfa from Ares-Serono. Each table of approved biologicals includes the generic and brand names, company marketing the product, and therapeutic areas of use.

BIOLOGICAL PRODUCT CATEGORIES

Over 60 products (biologicals) were marketed by over 30 companies in the United States from 1982 to 1999. In many diseases, biological products often have been major breakthroughs offering the first treatments where nothing previously was effective for serious diseases, i.e., dornase for cystic fibrosis or beta-interferon for multiple sclerosis. Now, we have biological products in more than 10 distinct categories.

Hormones

Three naturally occurring, protein-based hormones—insulin, growth hormones (somatotropin), and follicle stimulating hormone (follitropin)—have been duplicated

Interferons

These proteins called interferons are produced by many cells in the human body and serve to provide protection against foreign substances, such as infectious material. Interferons have several beneficial properties, such as stimulating the immune system and possessing cytolytic activity. Three families of interferons exist—alfa, gamma, and beta; and eight products have been created (Table 5). The indications (10) for interferons are broad, including oncology (e.g., malignant melanoma and chronic myelogenous leukemia), viral infection (e.g., hepatitis C), and immune diseases (e.g., multiple sclerosis).

Indications are added often to a molecule over time following the original product approval. Alpha-interferon is a very good example of this drug development process. The first indication was hairy cell leukemia in 1986,

Table 4 Approved biologicals (hormones)

Generic name	Brand name (company)	Therapeutic area
Human insulin	Humulin (Eli Lilly)	Insulin-dependent diabetes mellitus
	Novolin (NovoNordisk)	
Human growth hormone	Protropin (Genentech)	Growth hormone deficiency
	Humatrope (Eli Lilly)	Growth retardation in chronic renal disease
	Nutropin (Genentech)	AIDS wasting
	Saisen (serono)	
	Serostim (Serono)	
	Gentropin (General Biotechnology)	
	Norditropin (NovoNordisk)	
Follitropin beta (FSH)	Follistim (Organon)	Ovulatory failure
Follitropin alfa (FSH)	Gonal-F (Ares-Serono)	Ovulatory failure
Growth hormone releasing hormone	Geref (Serono)	GH deficiency in children

Table 5 Approved biologicals (interferons)

Generic name	Brand name (company)	Therapeutic area
Interferon alfa	Wellferon (Glaxo Wellcome)	Chronic hepatitis C
Interferon alfa-2a	Roferon-A (Hoffmann-La Roche)	Hairy cell leukemia; AIDS-related Kaposi's sarcoma; chronic myelogenous leukemia
Interferon alfa-2b	Intron A (Schering-Plough)	Hairy cell leukemia; AIDS-related Kaposi's sarcoma; Chronic hepatitis, types B and C; Condylomata acuminata; Malignant melanoma; nonhodgkins lymphoma
Interferon alfa-n3	Alferon N (Interferon Sciences)	Condylomata acuminata
Interferon gamma-1b	Actimmune (Genentech)	Chronic granulomatous disease
Interferon beta-1b	Betaseron (Berlex)	Acute relapsing-remitting multiple sclerosis
Interferon beta-1a	Avonex (Biogen)	Acute relapsing-remitting multiple sclerosis
Interferon alfa con-1	Infergen (Amgen)	Hepatitis C (Naive and Relapse)

Table 6 Approved biologicals (growth factors and interleukins)

Generic name	Brand name	Therapeutic area
Epoetin alfa	Epogen (Amgen) Procrit (Ortho Biotech)	Certain anemias from chronic renal disease; Zidovudine-induced anemia; cancer chemotherapy; anemia in surgery patients
Filgrastim (r-metHuG-CSF)	Neupogen (Amgen)	Neutropenias due to myelosuppressive chemotherapy; myeloid reconstitution after bone marrow transplantation; severe chronic neutropenia; peripheral blood progenitor cell transplant; induction and consolidation therapy in AML
Sargramostim (r-HuGM-CSF)	Leukine (Immunex)	Myeloid reconstitution after bone marrow transplantation; bone marrow transplant failure; adjunct to chemotherapy in AML; peripheral blood progenitor cell transplant
Becaplermin (PDGF)	Regranex (Ortho-McNeil)	Diabetic foot ulcer
Aldesleukin (IL-2)	Proleukin (Chiron)	Metastatic renal cell carcinoma; metastatic melanoma
Oprelvekin (IL-11)	Neumega (Genetics Institute)	Thrombocytopenia due to chemotherapy

Table 7 Approved biologicals (monoclonal antibodies)

Generic name	Brand name	Therapeutic area
Trastuzumab	Herceptin (Genentech)	Metastatic breast cancer (Her 2 Neu+)
Palivizumab	Synagis (MedImmune/Abbott)	Prevention of respiratory syncytia viral and fatal pneumonia in children
Infliximab	Remicade (Centocor)	Crohn's disease
Muromonab- CD3	Orthoclone OKT 3 (Ortho Biotech)	Acute allograft rejection in renal transplant patients; heart and liver transplant rejection
Abciximab	ReoPro (Centocor/Eli Lilly)	Prevention of blood clots after PTCA, unstable angina prior to PTCA
Rituximab	Rituxan (IDEC/Genentech)	Low grade non-Hodgkins lymphoma
Daclizumab	Zenapax (PDL/Roche)	Kidney transplant, acute rejection
Basiliximab	Simulect (Ligand/Novartis)	Acute organ transplant rejection

which was followed by seven additional uses. Extensive clinical trials (Phases 2 and 3) are required to establish each use.

Growth Factors and Interleukins

These proteins can be divided into three areas: blood cell growth factors (GFs), also known as colony stimulating factors (CSFs), tissue growth factors, and interleukins, which help communicate between cells. Eight CSFs are available worldwide: filgrastim, sargramostim, molgramostim, regimostim, lenograstim, and nartograstim, which stimulate white blood cell production and activity. Epoetin products (epoetin alfa and epoetin beta) reverse anemia by stimulating red blood cell production. Becaplermin is a tissue growth factor for the epidermis, being used to accelerate wound healing in diabetic ulcers (see Table 6).

Two interleukins are in use for renal cell carcinoma (IL-2) and for thrombocytopenia (IL-11). These products carry substantial multiorgan, especially cardiovascular, toxicity.

Monoclonal Antibodies

In the late 1990s, the monoclonal antibody proteins greatly expanded with six product approvals in a wide range of indications. In addition to kidney transplants, new uses include prevention of blood clots, metastatic breast cancer, non-Hodgkins lymphoma, Crohn's disease, and viral pneumonia in children. The growth in products with major new indications is predicated on humanization of the murine antibodies leading to less side effects and more affinity for the target receptors (more potential desired activity; see Table 7).

Enzymes and Blood Coagulation Factors

The first protein enzyme developed in the late 1980s was alteplase (t-PA), used to minimize complications due to blood coagulation in acute myocardial infarction. Three further enzymes were developed for similar indications. A unique enzyme was discovered for cystic fibrosis, dornase alfa, which is the enzyme deficiency responsible for the etiology of this disastrous disease. Blood factors (F.8, F.9, and F.7) are involved in normal blood coagulation. Their

Denileukin diftitox	Ontak (Ligand)	Cutaneous T-cell lymphoma

deficiency leads to bleeding disorders, but it is fully correctable through replacement therapy with these r-DNA proteins (see Table 8).

Other Biological Products

Tables 9 and 10 list a myriad of different product types for many unique indications. Two vaccines exist for hepatitis B and Lyme disease. Five liposomal products are available for oncologic and fungal uses. Cell therapies involve harvesting human cells or tissue, growing them *ex vivo*, and returning them to patients to heal damaged tissues, e.g., for wound healing and cartilage damage. Hyaluronic acid products are used during surgery, being placed between or around tissues preventing adhesions. An antisense molecule (fornivirsen) is used to treat CMV retinitis. The destructive tumor necrosis factor is blocked by etanercept to improve rheumatoid arthritis treatment. A fusion molecule combines interleukin-2 with a toxin to treat a rare cutaneous cancer. A peptide of four amino acids (glatiramer) is used to treat multiple sclerosis. A biological carrier (wafer) is used to administer the cancer drug, BCNU, for brain tumors.

FORMULATION AND DISTRIBUTION ISSUES

Most biological products (75%) are proteins, which as described earlier are large, complex, delicate molecules. Breakdown of proteins can occur through many mechanisms, also noted earlier. Furthermore, the final formulations often are sensitive to temperature extremes, which can cause precipitation. Restrictions in diluents exist because of potential adverse changes in stability. The protein formulations usually do not contain preservatives because of their interactions with

proteins, leading to single-use vials. Refrigeration usually is needed to achieve maximal shelf life. Prior to administration, vials should be warmed to room temperature to lessen local reactions.

PRODUCT PIPELINE

The future of biotechnology is expected to involve many product approvals. As of the year 2000, over 700 molecules are undergoing clinical studies, with many more in basic research. The approximately 1250 biotechnology companies in the United States are investing about \$10 billion annually in research. The types of products in development are quite varied, with monoclonal antibodies and vaccines comprising the largest categories (Table 11). The therapeutic areas being treated cover most diseases, with cancer uses comprising the most common research area (Table 12).

BLOW-FILL-SEAL—ADVANCED ASEPTIC PROCESSING

Deborah J. Jones

Norton Steripak, Cheshire, United Kingdom

INTRODUCTION

Blow-Fill-Seal (BFS) technology was developed in the early 1960s and was initially used for filling many liquid product categories, such as nonsterile medical devices, foods, and cosmetics. The technology has now developed to an extent that BFS systems are used today throughout the world to successfully aseptically produce sterile pharmaceutical products, such as respiratory solutions, ophthalmics, and wound care products.

BFS is an advanced aseptic processing technique within which plastic containers are formed by means of molded extruded polymer granules that are filled and sealed in one continuous process. This differs from conventional aseptic processing where container formation, preparation, sterilization, and container filling and closure are all separate processes.

Due to the level of automation of the entire process, very little human intervention is necessary during manufacture as compared to traditional aseptic filling. This is considered an advanced aseptic filling process. It is therefore possible to achieve very high levels of sterility confidence with a properly configured BFS machine designed to fill aseptically.

OUTLINE OF THE BFS PROCESS

The pharmaceutical BFS process combines the formation of plastic containers by blow/vacuum molding extruded pharmaceutical grade polymers, with an aseptic solution filling system.

Polymer granules are continuously fed to a machine hopper through an adiabatic screw extruder. Within the extruder the polymer is subjected to high temperature (generally greater than 160°C) and pressure (up to 350 bar) and becomes molten. It is then extruded through a die and pin set to form an open-ended tube of molten polymer known as a parison. The parison is supported by sterile air (parison support air) that is fed into the center of the parison through a sterilizing grade air filter fed with oil free compressed air. The parison is held in position by a parison clamp, which on some machines also serves to seal

the bottom of the parison. A mold set in two halves then moves over to the parison and closes around it. Molding is facilitated by vacuum slots in the mold. The molded plastic is severed from the continuously extruding parison by a hot knife, and is then shuttled within the mold set to the filling position.

The filling mandrels are comprised of a set of filling tips that are held within a protective air shower; this is a small area within the filling machine that is typically fed with sterile filtered air. When the molds are beneath the air shower, the filling tips are lowered into the neck of the partially formed container and the containers are filled. The mandrels then return to the protective air shower, and the containers are sealed by a second mold set (head mold), which forms the neck and closure of the BFS containers.

The entire cycle takes only a few seconds and therefore, results in minimal exposure of the open container to the surrounding clean room/air shower environment. The mold then opens and the filled containers surrounded by excess polymer are released. Excess plastic is then removed (typically this is done on-line by means of a mold specific cropping tool).

Liquid product is fed to the BFS machine from a holding tank or vessel. The product pathway is sterilized in place prior to receiving product, and product is sterilized by means of in-line sterilizing grade filters. Usually more than one stage of sterile filtration is on the product pathway.

FILLING ENVIRONMENT

Aseptic BFS machines are housed within classified clean areas of a minimum specification of class M5.5 (Federal Standard 209E) for 0.5 μm particles and greater (or equivalent), at rest. The new generation of BFS machines also is capable of operating with significantly decreased particle levels. The localized filling environment, or “air shower,” is of a higher classification, which meets the specification of class M3.5 (FS 209E) for 0.5 μm particles and greater.

Total particle levels should meet the required specifications and be measured, with the machine at rest, at defined

intervals by means of a laser particle counter (or other suitable instrument) to demonstrate continued compliance.

Levels of viable contamination, however, are of importance in operation. Microbiological monitoring for viable contaminants should be carried out to coincide with routine manufacture with normal levels of dynamic activity. As with traditional aseptic filling, viable contamination within the clean area should be controlled by means of an effective routine cleaning and disinfecting program and the adoption of appropriate clean room behaviors and practices by trained personnel. BFS technology has the advantage of being able to operate without continuous personnel presence within the clean area. However, operators will need to enter the area to start up the machinery and to attend to the machine as necessary to make routine adjustments. It is a requirement within the European forum that clean room garments worn to enter the class M5.5 (FS209E) clean room be of a standard appropriate for a higher (M3.5) classification clean room.

A routine microbiological environmental monitoring program should be established and documented based on historical and operational data to demonstrate continued compliance with specifications, as well as to monitor trends. A typical monitoring regime within the clean room would include quantitative air and surface monitoring. Semiquantitative air monitoring by the use of settle plates also is useful in supplying data associated with a longer period of time in operation (up to 4 h exposure). Recommended limits for viable contaminants (not specific to BFS processes) in clean rooms are quoted in various guidelines, including the current United States Pharmacopoeia (USP) and directive 91/356/EEC (MCA rules and Guidance for Pharmaceutical Manufacturers and Distributors 1997, Annex 1) (see Table 1). Alert and Action levels should be clearly defined based upon both operational data and published recommendations.

Consideration should also be given to monitoring the localized filling zone (air shower). Although access to this area will be prohibited (and also extremely dangerous) during operation, some monitoring for viable and nonviable contaminants may be possible at rest (e.g., at the end of a product batch). It may also be feasible to install a remote means of obtaining samples during operation.

MEANS OF BFS CONTAINER CONTAMINATION FROM THE ENVIRONMENT

As previously stated, for aseptic BFS, container filling occurs in a localized air shower provided with sterile filtered air. However, there is a short period of time between container formation and filling when the open container is transferred from the parison formation position to the filling position, and when the open container is exposed to the clean room environment. Therefore, it may be possible for contaminants from the room environment to enter the container during this shuttling period.

Air used to form the parison (parison support air) is typically sterile filtered air. If this is not the case, non-sterile air may be able to enter the parison during parison formation.

It was demonstrated during a simple practical experiment that broth filled units (totaling over 44,000) manufactured over several days in a highly contaminated environment remained sterile (1). The environment was contaminated by means of high levels of personnel activity in order to generate contaminants in keeping with those generated under normal conditions (albeit at grossly elevated levels).

During a more controlled study carried out within an environment artificially contaminated with high levels of individual nebulized spores of *Bacillus subtilis* (2), a level of contamination within the environment was achieved that led to the contamination of broth filled units. The results were extrapolated to suggest a contamination rate of 1 unit in 4×10^6 , with a surrounding environmental contamination of 1 cfu/m³.

Routes of air-borne contamination into BFS containers were investigated during a study using Sulfur hexafluoride (SF₆) tracer gas (3). During this experiment, the tracer gas was released at a known concentration into a clean room that housed an aseptic BFS machine. Levels of the tracer gas were then measured within subsequently filled BFS units. The study concluded that the container was effectively protected by the localized air shower. Although not necessarily representative of deposition of microbial

Table 1 EU and USP guidelines for clean room microbial limits

Classification	Air (cfu/m ³)	Settle plates (cfu/4 h)	Surface samples (cfu/55 mm diameter plate)
EC grade C	100	50	25
USP grade M5.5	20	not specified	10 (floors) 5 (other surfaces)

contaminants, there also was conclusive evidence of some room air within the BFS containers. The control of environmental contamination within the clean room is therefore important.

Extensive process simulation (broth fill) results for BFS effectively demonstrate that high levels of sterility confidence can be obtained with a properly configured and validated machine. However, in order to maintain high levels of sterility assurance, it is important that levels of microbial contamination are controlled within the filling environment.

CONTAMINATION FROM PRODUCT COMPONENTS

As with traditional aseptic filling, in order to comply with pharmaceutical good manufacturing practices (GMP), it is important to minimize contamination at all stages of manufacture. Raw materials should be of a high quality and tested for microbial contamination. Water used for product manufacture should be of low bioburden and high purity (preferably water for injection quality, although this requirement is dependent upon the nature of the product being manufactured).

A program of bioburden testing for each product batch at various stages of manufacture should be established and documented. This will be dependent upon the manufacturing process, but as a minimum should include bioburden analysis of bulk solutions prior to any sterile filtration. The maximum life of the bulk solution in a nonsterile environment (generally within a mixing tank) should be limited to prevent increase in bioburden beyond an acceptable level. Bioburden testing at this stage should be carried out on samples taken at the end of the holding period to give “worst case” data.

BFS technology often results in considerable machine down time, especially as associated with activities such as Clean In Place (CIP) and Steam In Place (SIP), in order to prepare a machine for manufacture. Initial machine adjustments will then be necessary in order for integral and cosmetically acceptable units of the correct fill volume to be consistently produced. It, therefore, can be advantageous to fill larger product batches once this is achieved. In order to facilitate this with respect to maintaining a low bioburden throughout all stages of liquid processing, it is a common practice to have a sterilized storage vessel into which bulk product is filtered through a sterilizing grade filter. This sterilized bulk solution can then be used to feed the filling machine without escalation of microbial levels. Further stages of

sterile filtration are required on the filling machine closer to the point of fill. A facility for sampling products during the course of the filling stage prior to further filtration can be incorporated. This will give data to confirm the low/zero bioburden of the product prior to the final stages of filtration, during the course of a longer batch.

The BFS container is produced from high-grade virgin polymer granules. Studies have investigated the lethality of the extrusion process with respect to container sterilization, the most recent of which is discussed in the validation section. Bioburden testing of polymer granules can be carried out in order to establish base line data. Virgin polymer granules, if handled and stored correctly, should be of very low bioburden.

EQUIPMENT—INTERVENTIONS AND MAINTENANCE

In order to produce sterile pharmaceutical products with a high degree of sterility confidence, it is of key importance that the equipment be operated by experienced and trained personnel with a full understanding of both the technology and aseptic processing. Operator intervention during machine operation is limited due to the nature of the technology; however, BFS machines are complex and some operator activity will be required from time to time during normal manufacture. Clearly documented rules are imperative in order to clarify which activities are prohibited during batch manufacture and which are permitted. For example, if a fault occurs that requires immediate corrective action involving the sterile product pathway, or within the direct vicinity of the filling zone, these would typically be prohibited activities that would lead to termination of the product batch. Activities such as parison and fill volume adjustments are part of the normal operation of the machinery and are permitted. A proceduralized means of documenting these activities should exist, however routine they may be.

Interventions should be categorized according to their potential for affecting the product being manufactured, and only those with no risk to product sterility should be permitted during operations.

As with all machinery, BFS machines must be properly maintained in order to maintain effective operation with the minimum of operator activity. A documented preventative maintenance program should be in place and specify appropriate frequencies for all machine components and associated systems and services. Maintenance activities should ensure that moving parts are sufficiently (but not overly) lubricated,

and that excess lubricants are removed at regular intervals to maintain the cleanliness of the machine. Abrasion among moving parts, particularly hoses and flexible pipe work, can be a problem with BFS machines and can cause undesirable particle generation and leaks that lead to unplanned maintenance and downtime. Moving parts should be inspected at regular intervals to avoid abrasion and to check for wear and tear. Regular seal changes with reconciliation of new/old seals should also be included.

Coolant systems are an integral part of container formation and serve to cool the molds and, if applicable, the parison clamp assembly. Coolant, although not in direct contact with product pathways, is in close proximity to the containers, and maintenance should be carried out to prevent coolant leakage. Coolant systems are prone to microbiological contamination and should be routinely treated to keep the bioburden under control. Coolant systems should be regularly sampled and tested for bioburden to ensure continuous compliance to a predefined specification.

VALIDATION OF BFS SYSTEMS

BFS machinery and associated equipment for aseptic manufacture should be constructed in such a way that the product pathways are of hygienic design with hygienic valves and minimal joints to facilitate cleaning and sterilizing in place.

Clean in Place (CIP)

As for all machinery involved in aseptic manufacture, CIP is necessary for all equipment that has product contact. This would typically include a bulk mixing tank, transfer lines, and the BFS machine itself, and may also include a holding vessel with associated transfer lines. CIP validation should be carried out to establish routine CIP practices that will clean the manufacturing equipment so that no contamination of subsequent products manufactured that would alter the safety, identity, quality, or purity of the drug beyond the predetermined requirements can occur. CIP procedures should be established by cleaning validation following the manufacture of worst case products (i.e., those that are most difficult to remove down to acceptable levels due to their solubility or activity). Means of measuring CIP efficacy include analysis of swabs taken directly from product contact machine parts and analysis of rinse waters. When establishing areas for swabbing, the specific equipment design needs to be taken into account, and those areas that

are potentially most problematic should be selected for analysis (e.g., filter housings or areas that may cause product hold-up).

Steam in Place (SIP)

Aseptic BFS machines are subject to SIP sterilization following standard CIP cycles. SIP cycles are routinely measured by thermocouples located in fixed positions along the product pathway. Validation of SIP cycles should be carried out to demonstrate that consistent sterilization temperatures are achieved throughout the equipment in order to prove that the system can be effectively sterilized. Validation should also identify suitable positions for routine use, or justify the fixed probe positions already in place. SIP validation is generally carried out using additional thermocouples and should include the use of Biological Indicators (appropriate for moist heat sterilization). Test locations should include areas that may be prone to air or condensation entrapment. An accurate engineering line drawing of the system in order to aid identification of suitable test locations and to document test locations selected should be available.

Qualification of Aseptic Filling

The standard and most appropriate method for the qualification of aseptic filling is by means of a broth fill (or media fill). Using this method, units of liquid microbiological growth media (usually a full strength general-purpose media, such as Tryptone Soy Broth), are filled and incubated. Following an appropriate incubation period, the units are inspected for contamination. In this way, an indication of the level of contamination during the filling process can be evaluated.

There is no appropriate defined sterility confidence level that can be translated directly into acceptance criteria for broth fill contamination for BFS processes. The most commonly recognized acceptance criteria is a sterility assurance level (SAL) of 10^{-3} , although it is accepted that modern aseptic filling techniques such as BFS can achieve a higher SAL and that this should be reflected by broth fill results and acceptance criteria for this recognized advanced technology.

Broth fills should be a major part of the operational qualification of a new BFS machine to demonstrate aseptic processing capability prior to product manufacture (typically three successful consecutive broth fills are required) and should be carried out at defined intervals thereafter.

Broth fills should be carried out under conditions that are representative of those during normal operation. If there is to be a deviation from routine processes, it should only be in the direction of presenting a greater, rather than a lesser, challenge to the process. Due to the level of automation of BFS technology, it is extremely difficult to take “extra care” in order to reduce the chance of container contamination during a broth fill; therefore, results are not as operator-dependent as other less automated aseptic manufacturing processes.

New facilities should contain some background environmental monitoring data. It is important that environmental monitoring data be obtained during the course of broth fill batches to demonstrate a normal level of environmental contamination—the validity of broth fill results carried out in an environment having consistently lower contamination levels than those obtained during routine batch manufacture could be questioned.

Batch manufacture, storage, and transfer should be carried out in accordance with routine procedures and with the same operators. The machine should be cleaned and sterilized as normal, although if an overkill cycle is used routinely for sterilization, a partial sterilization (although still meeting standard sterilization parameters) may be chosen as “worst case.”

Broth filled BFS units should generally meet all of the necessary product acceptance criteria, such as fill volume, wall thickness, container integrity, and cosmetic acceptability. The necessary operator activity at the start of a product batch is arguably more intrusive than at any other stage of manufacture. Product units routinely produced at the very start of a batch will usually be discarded due to fill volume, cosmetic, or other deficiencies as the machine set-up is adjusted. However, during a broth fill, it is a good practice to retain and incubate all start-up units (except any leaking units) to demonstrate that start-up activities have not affected product sterility. Such units should be segregated from the subsequent units that meet the acceptance criteria and labeled accordingly.

In addition, it can be useful to retain and incubate reject units filled during the course of a broth fill batch (again, excluding leaking units) for additional information. Again, these should be segregated from acceptable units and labeled accordingly. Although such units would be rejected during normal production, microbial contamination found in such units can be indicative of a problem that requires attention.

During the course of a broth fill, operator activity will be necessary as with routine manufacture. However, additional activities can be carried out to cover all permissible activities in order to provide evidence that

product sterility is not affected. Such interventions should be planned and documented with the batch documentation.

Frequency and size of broth fills must be clearly defined. Size of fill is usually based upon the statistical probability of detecting an acceptably low incidence of microbial contamination. Tables have been published to this effect (4), but the BFS operator must decide both the size and frequency of broth fills based upon their specific facility, routine product batch sizes, and operation. For high-speed BFS machines, filling routine product batches in excess of 100,000 units, relatively large broth fill batches, in comparison with traditional aseptic filling lines, are both feasible and appropriate.

The internal surfaces of broth filled units should be fully wetted to ensure capture of any contaminants within the broth. This is commonly achieved by agitation or inversion of the units either prior to or during the incubation period.

Incubation time and temperature should be such that macroscopic microbial growth of a wide range of common isolates will be detected. This should be routinely demonstrated by including positive control units inoculated with a low level of compendial microorganisms. It is desirable to perform additional testing to demonstrate that the incubation time and temperature selected will promote the growth of isolates obtained from machine operating environments. The Pharmaceutical BFS Operators Association recommends incubation of 14 days at 25–32°C.

Broth fill data from various BFS users were put together during a survey carried out in 1998 by the Pharmaceutical BFS Operators Association. These results, together with some more recent data, can be found in Table 2.

Some of the media fills carried out were full production batch volumes with hundreds of thousands of units filled in a single batch. In addition to the figures within the table, a run of over 1,500,000 units was recorded with the detection of a single contaminated unit.

It is clearly impractical to carry out very high numbers of broth filled units on a routine basis, but if unpreserved products are manufactured, and if practicable, it is good practice to fill broth directly following product batches with no further machine flushing or sterilization.

Given the high performance demonstrated during media fills, acceptance criteria should be based upon what can be realistically achieved. During broth fills of a standard size, any incidence of contamination among the units filled should lead to an investigation. In the absence of a cause, even with very low levels of contamination, consideration should be given to machine recommissioning.

Machine recommissioning should also be carried out if modifications to a filling machine have been made that

Table 2 BFS broth fill data

Company	A	B	C	D	E	F
Total number of units filled	6,462,570	222,900	2,697,496	1,534,626	1,042,254	31,600
Total number of nonsterile units detected	3	0	0	0	0	0
Contamination rate	0.0005%	0%	0%	0%	0%	0%

Positive units, assigned a definitive cause and unrelated to the BFS process as practiced during routine product manufacture, have not been included.

EC grade C is the closest classification to Federal Standard grade M5.5 (FS209E). In both cases, the limits specified are guidelines only and not regulatory requirements.

may have an effect on process capability (e.g., changes to the sterile product pathway or air shower).

BFS Containers

The BFS container is formed as an integral part of the process from medical grade virgin polymer granules. A recent study (5) investigated the lethality of the extrusion process when challenged with a high bioburden of spores. The spores of the test organism *Bacillus subtilis* var. *niger* were selected as they are known to be resistant to dry heat; the same strain was selected as the organism of choice for Biological Indicators used in dry heat sterilization processes. A series of broth fills were carried out using polymer batches inoculated with various levels of spores between 2×10^1 and 2×10^5 spores per gram. The broth filled units were then incubated in line with the company's routine broth fill procedure (25–32°C for 14 days). Spore contamination of units was observed with batches of polymer inoculated with high spore levels. The experiment demonstrated a relationship between polymer contamination and product contamination that was dependent upon both the level of contamination in the polymer and the resistance of the contaminant (in terms of D-value) to dry heat sterilization. The study also demonstrated inactivation of the spores on the granules with strong evidence of lethality associated with the extrusion process.

Routine bioburden testing of virgin pharmaceutical grade polymer granules tends to give very low or zero counts per gram of polymer tested, with contaminants generally much more heat labile than *Bacillus subtilis* spores. The study detailed was also carried out using a BFS machine adjusted to extrude at the lower end of the operating temperature range for extrusion. Therefore, it can be concluded that the extrusion process renders the contaminants unavailable, with sufficient bioburden reduction/inactivation for it to be appropriate for aseptic formation of BFS containers. This is further endorsed by routine broth fill data.

The closures of BFS containers are formed within the automated process by the head mold set which closes around the top of the severed section of parison following filling. The integrity of the container and closure is generally tested by a manual or automated method of leak detection performed outside of the filling environment following removal of excess plastic (deflashing) from the filled product units.

In order to minimize the number of leaking units produced, it is important that mold sets are correctly aligned. Very slight misalignment of molds may potentially lead to the production of units with very slight leaks that may be difficult to detect by routine methods. Therefore, correct molding is of key importance and usually can be checked easily by careful and experienced visual examination of units.

Container integrity testing can be carried out very effectively by a bacterial challenge test. Using this method, sterile broth filled units are submerged for a period of time (e.g., 24 hours) within a buffered solution that contains a high level bacterial challenge. (There are no regulations or guidelines that specify which organism to use, but it would seem logical to use a factory isolate or a relatively small organism such as a *Pseudomonas spp.*) Units are then removed, incubated, and checked for growth of the challenge organism. An absence of growth shows an integral unit and closure. This method is extremely sensitive and although this is not a test that is practical to perform on a routine basis, it can be a useful tool for infrequent use.

Filtration

Hydrophilic and hydrophobic sterilization grade filters are used throughout the BFS process for the sterilization of product and air, respectively. Filters should be purchased from an approved supplier and should be certified as meeting the regulatory requirements for sterilizing grade filters. By definition this means that the filter will have

full bacterial retention when subjected to an aqueous challenge of *Brevundimonas diminuta* (ATCC 19146) at a minimum concentration of 1×10^7 cfu/cm² of filter surface area.

Hydrophobic filters do not come into direct product contact and, therefore, the standard bacterial retention test alone generally is sufficient validation. However, as hydrophilic filters are in direct product contact, additional validation will be necessary for each product type in order to demonstrate that the filters selected for product sterilization do not alter the safety, identity, strength, quality, or purity of the drug product. Qualification of hydrophilic filters will also be necessary in order to demonstrate that the specific product type, in conjunction with a bacterial challenge, does not affect the efficacy of the filter. Validation of filters by means of bacterial retention tests requires specialist equipment and is often arranged between the filter manufacturer and the BFS operator.

SUMMARY

Aseptic pharmaceutical BFS technology for the manufacture of sterile liquid products demonstrates high levels of sterility assurance when correctly operated and configured. The technology is continually improving as more expertise is developed.

However, an understanding of the means of potential container contamination and the implementation of systems operating to minimize these means is important in order to maintain the high standards achievable with this technology.

CALORIMETRY IN PHARMACEUTICAL RESEARCH AND DEVELOPMENT

INTRODUCTION

Calorimetry is the measurement of energy changes within a material that are either manifested as exothermic (heat liberating) or endothermic (heat consuming) events (Table 1). Changes in energy (not absolute energies) are conventionally determined, and quantitative measurements may be made if the mass of the sample(s) is accurately known. Advanced and some custom-built instruments may permit the simultaneous monitoring of energetic changes along with other physicochemical events (e.g., changes in mass). These include, for example, microscopy Differential Scanning Calorimetry (microscopy-DSC) (1).

The most common applications of calorimetry in the pharmaceutical sciences are found in the “sub-fields” of DSC and Microcalorimetry. State-of-the-art DSC instruments and microcalorimeters are extremely sensitive and are powerful analytical tools for the pharmaceutical scientist.

DSC usually involves heating and/or cooling samples in a controlled manner, whereas microcalorimetry maintains a constant sample temperature. DSC instruments are considered to be part of the “Thermal Analysis” armamentarium; for additional information the reader should refer to the Thermal Analysis section of this book.

The beginning of this article gives a brief introduction into thermodynamics. A description of differential scanning calorimetry, which includes instrumentation, calibration, and applications, follows. A section on microcalorimetry is next, with a brief introduction into microcalorimetry, instrumentation, calibration, and applications. The article ends with a general comment on the regulatory aspects of calorimetry. A general description of the underlying physical or chemical transitions/reactions can be found in the section on DSC.

THERMODYNAMICS

The field of calorimetry relies on the principles of thermodynamics; the next section provides a brief overview of the general principles. References are provided for those who are unfamiliar with thermodynamics (2, 3).

A calorimeter consists of a container that is isolated from its exterior surroundings, where the heat exchange that occurs between the system and the environment can be measured. The “environment” is defined as the calorimeter and its contents, and the “system” is either a chemical reaction or physical change of state. The system can either absorb (endothermic) or lose energy (exothermic) to or from the environment. Exothermic changes will require the temperature of the environment to increase since it is the environment that is receiving the energy lost by the system. The energy of an isolated system remains constant and the energy exchange of the system must be equal but opposite in sign to the energy of the environment (First Law of Thermodynamics, Conservation of Energy). Endothermic changes in the system will involve a decrease in temperature of the environment since the environment is providing the energy absorbed by the system.

Based on the assumption that the system is closed, which is usually the case in differential scanning calorimetry and microcalorimetry, any reaction or change in state is independent of the path and can be subdivided into small reversible steps (Hess’ Law of Summation) (2, 3). The First Law of Thermodynamics states that energy may neither be created nor destroyed. It defines the internal energy, dU , as the sum of the change in heat that has been transferred to the system, dq , and the work done on the system, dw .

$$dU = dq + dw \quad (1)$$

When operated at constant pressure, Equation (1) can be written in terms of the enthalpy, H . The total energy exchange between the system and the environment, the

Table 1 Common thermal events that can be detected using calorimetric techniques

Event	Example
<i>Endothermic</i>	
Fusion	Melting of drug substances; purity evaluations
Vaporization	Evaporation of liquid or semisolid excipients
Sublimation	Removal of frozen water during lyophilization
Desorption	Drying of wet granulated formulations
Desolvation	Removal of stoichiometric water from crystalline hydrates
<i>Exothermic</i>	
Crystallization	Solvent vapor induced crystallization of amorphous excipients
Precipitation	Formation of salt forms of drug substances
Solidification	Melt granulation with semisolid excipients
Adsorption	Solvent vapor sorption by drug substances
<i>Chemisorption</i>	
Solvation	Water vapor sorption by excipients
Curing of resins	Curing of polymeric packaging materials
<i>Other</i>	
Glass transition	Variation of glass transition temperature with water content
Relaxation of glasses	Enthalpic recovery of amorphous drug substance upon storage or annealing
Decomposition	Thermal decomposition of drug substance
Dissolution	Dissolving drug substance in dissolution media
Complexation	Complex formation between drug and cyclodextrin

enthalpy change (dH), is the sum of the change in internal energy of the system, dU , and the change in the amount of work, PV :

$$dH = dU + PdV \quad (\text{at constant pressure}) \quad (2)$$

At zero net work and negligible change in volume (a close approximation for solids and liquids), the equation reduces to

$$(dU)_p = (dH)_p = (dq)_p \quad (3)$$

Thus, the enthalpy is effectively equal to the heat added or lost from the system, and changes in enthalpy can be measured directly in a calorimeter as dq (heat flow).

The heat exchange, dq , entering or exiting the system is equal to the change in enthalpy, dH , which is related to the heat capacity, C_p :

$$dq = dH = \int_{T_2}^{T_1} C_p dT \quad (4)$$

The increase in temperature of the system (from T_1 to T_2) is a function of its heat capacity. If C_p is large, then the transfer of a given amount of heat to a system results in only a small temperature increase.

DIFFERENTIAL SCANNING CALORIMETRY

During DSC, differences in heat flow between a sample and a reference are measured as a function of time and sample temperature. DSC analysis allows quantitative and qualitative information to be obtained about the physical and chemical changes that occur in a sample. DSCs are used extensively in the pharmaceutical industry to determine the melting points, purity, and glass transition temperatures of materials.

Instrumentation

Two types of differential thermal instruments, similar in practice but different in concept, are commercially available—differential thermal analyzers (DTA) and differential scanning calorimeters (DSC). Both techniques consist of a sample and reference pan, and provide quantitative and qualitative information on important physical phenomena of the sample (melting, purity, glass transition, etc.). These techniques differ both in sensitivity and the type of information that is recorded. DSC is a calorimetric technique where energy differences are measured as a function of time and temperature. DTA is solely a thermal technique where temperature differences and not energy are recorded as a function of time and temperature (Fig. 1a) (4, 5).

Two principal DSC designs are commercially available—power compensated DSC and heat flux DSC. The two instruments provide the same information but are fundamentally different. Power compensated DSCs heat the sample and reference material in separate furnaces while their temperatures are kept equal to one another (Fig. 1b). The difference in power required to “compensate” for equal temperature readings in both sample and reference pans are recorded as a function of sample temperature. Heat flux DSCs measure the difference in heat flow into the sample and reference as the temperature is changed. The differential heat flow to

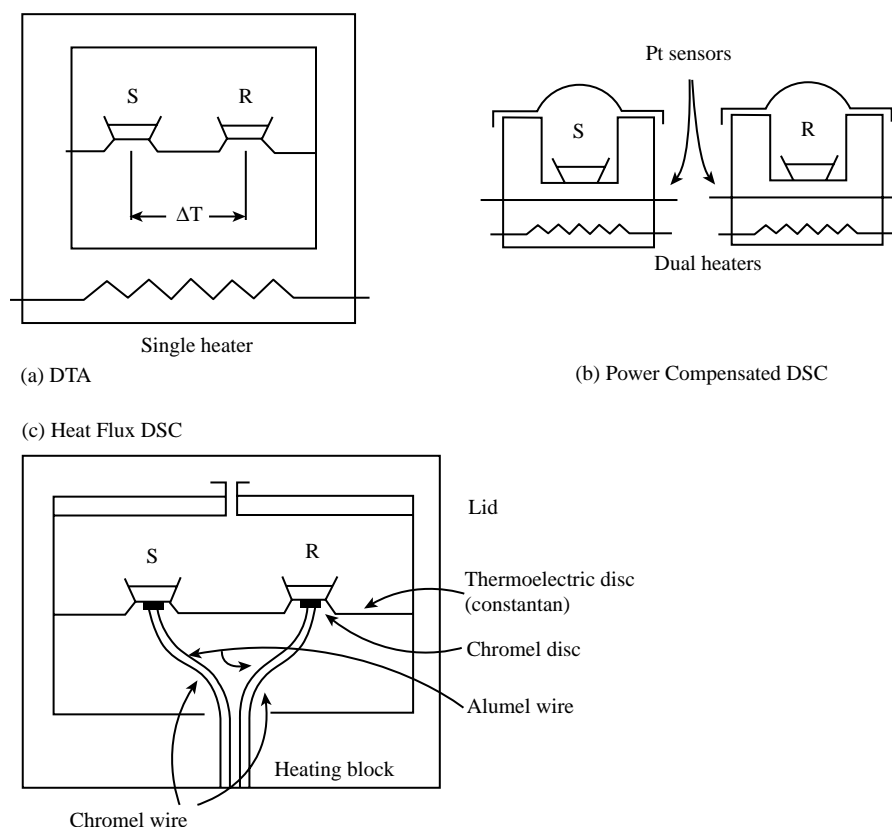

Fig. 1 Schematic diagrams of the (a) differential thermal analysis (DTA), (b) power-compensated differential scanning calorimeter, and (c) heat-flux differential scanning calorimeter cells (DSC) (adapted from DuPont Instruments Systems Brochure). (From Ref. 5.)

the sample and reference is monitored by chromel/constantan area thermocouples (Fig. 1c) (4, 5).

Modulated Differential Scanning Calorimetry/Dynamic Differential Scanning Calorimetry

Conventional DSC measures a sample's total heat flow. This total heat flow is comprised of a heat capacity component and a kinetic component (Eq. 5)

$$\begin{aligned} \text{total heat flow} &= \text{heat capacity component} \\ &+ \text{kinetic component} \\ dq/dt &= C_p dT/dt + f(T, t) \end{aligned} \quad (5)$$

where dq/dt = heat flow, C_p = heat capacity, dT/dt = temperature rate, $f(T, t)$ = heat flow from kinetic component as a function of temperature and time. Variations of conventional DSC have been used in order to extract additional information from these experiments. Two such techniques are Modulated Differential Scanning

Calorimetry (MDSC) and Dynamic Differential Scanning Calorimetry (DDSC). Unlike conventional DSC, MDSC and DDSC determine the total heat flow, dq/dt , and the heat capacity component of heat flow, $C_p dT/dt$. Equation (5) then leads to the indirect determination of the kinetic component of heat flow, $f(T, t)$.

MDSC, developed by TA instruments (New Castle, DE), is based on the conventional heat flux DSC furnace design. The temperature programs differ in that a sinusoidal modulation is overlaid on the conventional linear heating or cooling rate to produce a continuously changing nonlinear sample temperature. This can be viewed as running two experiments at once. The first experiment consists of heating the sample at a constant linear rate to obtain the total heat flow much like conventional DSC. During the second experiment, the heat capacity component of the heat flow is obtained by continuously varying the temperature sinusoidally with a zero net temperature change during the course of the modulation. The experimental parameters may be optimized by modifying three variables—the average heating rate, the period of modulation, and the temperature

amplitude of modulation. Fourier Transformation of the modulated heat flow signal is used to calculate an average heat flow value, which is similar to the total heat flow obtained by conventional DSC. The heat capacity is determined by the ratio of the heat flow amplitude to the modulated heating rate amplitude. The heat capacity heat flow is then obtained by multiplying the heat capacity by the average heating rate. The kinetic component heat flow is obtained by the difference between the total heat flow and the heat capacity component.

$$\begin{aligned} dq/dt = & C_p(dT/dt + A_T w^* \cdot \cos wt) \\ & + f'(t, T) + A_K(\sin wt) \end{aligned} \quad (6)$$

where $(dT/dt + A_T w^* \cdot \cos wt)$ = measured heating rate, $f'(t, T)$ = kinetic response without temperature modulation, A_K = amplitude of kinetic response to temperature modulation.

DDSC provides heat capacity and kinetic component information differently from MDSC. The temperature program consists of an "Iso-Scan" whereby the traditional heating rate program is combined with several isothermal holds or a "Heat-Cool" program, which consists of combined heating and cooling temperature programs. The user selects the appropriate method depending on the type of experiment being performed (6). From the dynamic component of the sample response, the complex heat capacity can be calculated. The complex heat capacity, C_p^* , is the vector sum of the storage, C_p' , and loss heat capacity, C_p'' . It is generally the same as the storage heat capacity except in the melting region where heat losses dominate. The storage heat capacity is associated with molecular motions within the sample in a manner similar to the storage modulus in dynamic mechanical measurements. The out-of-phase component, the loss heat capacity, C_p'' is associated with the dissipative properties

of the material. The loss heat capacity is out-of-phase with the temperature change because heat flow has resulted in molecular structural changes in the material. The loss tangent is the ratio of the loss heat capacity to the storage capacity and is a measure of the relative importance of each component (6).

$$C_p^* = C_p' + C_p'' \quad (7)$$

where C_p^* = complex heat capacity, C_p' = storage heat capacity, C_p'' = loss heat capacity. Some of the advantages and disadvantages of using MDSC are given in Table 2.

Sample Preparation and Calibration

DSC samples are generally analyzed in small metal pans that consist of inert or treated metals (aluminum, platinum, silver, stainless steel, etc.). Several pan configurations exist, such as open, pinhole, covered, or sealed. Reference pans should be made of the same material as the sample pan and in identical configurations. Typical DSC sample sizes are 3–5 mg for pharmaceutical materials. The material should completely cover the bottom of the pan to ensure good thermal contact. The pan should not be overfilled to prevent thermal lag from the bulk of the material to the sensor. Physically stable compounds that consist of large granular particles should be ground to reduce unwanted thermal effects. Accurate weights are imperative if quantitative data of the sample's energetic parameters are desired (5).

DSC is a scanning technique that usually is used for relative rather than absolute measurements. The meaningfulness of the results depends in the care taken in calibrating the instrument as close to the transition temperatures of interest as possible. The accuracy of any thermo-analytical instrument is strongly dependent on the

Table 2 Advantages and disadvantages of modulated DSC

Advantages	Disadvantages
Ability to differentiate overlapping transitions	More complex thermal lag effects
Increased resolution without loss of sensitivity	Not as precise linear heating rate
Measurement of heat capacity and heat flow in a single experiment	Many experimental parameters
Measurement of initial crystallinity	Not recommended for melting transitions.
Ability to study previous thermal history	Gives sample a complex thermal history
Ability to distinguish between reversible and nonreversible transitions	Sometimes difficult to interpret

use of high purity calibration standards. Well-defined standards are especially important when analyses are carried out using different instruments and at different times. In general, metal calibration standards, such as indium, tin, bismuth, and lead, are utilized due to ready availability and ease of use. Low melting metals, such as mercury and gallium, are used to a lesser extent because of toxicity and handling problems. Organic compounds have been recommended as standards when studying organic material to minimize differences in thermal conductivity, heat capacity, and heat of fusion (7–9). It is likely that metals will continue to be popular temperature and enthalpy standards due to availability and ease of use, and organic standards may be used predominantly at temperatures below 300 K (10).

DSC results are dependent on the calibration of the instrument, sample preparation, and sample configuration. Some researchers argue that power compensated DSCs need to be properly calibrated upon both heating and cooling at the same rates in order to maintain a high level of accuracy (11, 12). Standard procedures can be obtained from the American Society for Testing of Materials (ASTM). In addition, all results obtained by DSC are a function of the scanning rate used and should be reported with the scanning rate. The shape, the area of the transition or change of baseline, and particularly the temperature of the transition will be dependent on the scanning rate; it will move to higher temperatures with increasing heating rate. Increasing the scanning rate increases sensitivity, while decreasing the scanning rate increases resolution. To obtain thermal event temperatures close to the true thermodynamic value, slow scanning rates should be used (e.g., 1–5 K/min).

Definitions and Applications of DSC

The purpose of this section is to define the various parameters that are measured by DSC. The types of thermal events, exothermic or endothermic, that can be measured by DSC are reported in Table 1. The following sections will describe some of the more fundamental thermal events. Examples from the pharmaceutical field will be given to illustrate the techniques. The examples will be based on either single components, such as drug substance and bulk excipients, or on a mixture of components, such as physical blends of drugs and excipients, solid dispersions, formulated drugs after granulation, and/or compression.

Melting

Melting is a first order endothermic process by which the compound takes in a net quantity of heat (molar heat of

Fig. 2 DSC scan of sucrose showing the glass transition temperature, (T_g), recrystallization exotherm temperature (T_c) and enthalpy (ΔH_c), onset of melting (T_o), extrapolated melting onset (T_e), peak melting temperature (T_m), enthalpy of fusion (ΔH_f), and onset of degradation at 10 K/min. Endothermic transitions are shown down.

fusion). Through DSC, melting can be seen as an endothermic peak (Fig. 2). The broadness of the peak defines the purity of the crystalline compound undergoing melting, with the less pure and less perfect smaller crystals melting first followed by melting of the purer larger crystals (5). The melting temperature is the temperature at which the 3-dimensionally ordered crystalline state changes to the disordered liquid state. It is defined either as an extrapolated melting temperature onset, T_e , obtained at the intersection of the extrapolated baseline prior to the transition with the extrapolated leading edge, or as the peak melting temperature, T_m . Other temperatures that describe the melting process are the onset of melting, T_o , and the extrapolated end of the transition (5).

The enthalpy of fusion, ΔH_f , is obtained from the area of the endothermic transition. The area of the transition is affected by the selection of the baseline. The baseline is generally obtained by connecting the point at which the transition deviates from the baseline of the scan to where it rejoins the baseline after melting is completed. For some materials that undergo a significant change in heat capacity change on melting, other baseline approximations (such as a sigmoidal baseline) are used (5).

Purity

The purity of crystalline compounds can be calculated using the van't Hoff equation from the enthalpy of fusion and melting temperature obtained by DSC.

$$T_{s(i)} = T_e - RT_e^2 X / (\Delta H_f F_i) \quad (8)$$

where $T_{s(i)}$ is the sample temperature at equilibrium corrected for thermal lag effects (K), T_e is the melting temperature of the pure compound (K), R is the gas constant (8.314 J/mol/K), X is the molar fraction of impurity, ΔH_f is the enthalpy of fusion of the pure compound (J/mol), and F is the fraction of the sample that is molten at $T_{s(i)}$. The melted fraction is equal to the area of the section melted (A_i) divided by the total area of the melting endotherm (A_T) as shown in Fig. 3. The melting depression, $(T_e - T_{s(i)})$ is equal to the slope, $(RT_e^2/\Delta H_f)X$, of the straight line obtained when $T_{s(i)}$ is plotted as a function of $1/F_i$. The theoretical melting temperature is obtained on extrapolation to $1/F_i = 0$. A straight line may not be obtained due to thermal lag, sensitivity, lack of a eutectic point detection, and formation of solid solutions. In addition, a significant amount of material may have melted before a measurable heat flow is observed by DSC. As a result, a correction constant K_{corr} is added to the measured areas (each fraction) to correct the curvature of the plot of $T_{s(i)}$ as a function of $1/F_i$ (Eq. 9). The melting depression $(T_e - T_{s(i)})$ is then obtained when $F_i = 1$ (5).

$$1/F_i = (A_T + K_{\text{corr}})/(A_i + K_{\text{corr}}) \quad (9)$$

It is necessary that the melting curve is obtained with a calibrated DSC using small samples (1–3 mg) and slow scanning speeds ($<5 \text{ K/min}$, preferably 2 K/min). The

purity of a compound should be determined at several scanning speeds to ensure that the compound does not undergo any solid-solid transitions, such as polymorphic conversion or degradation (5).

The three advantages of obtaining purity by DSC are: 1) its speed of measurement; 2) the type of impurity does not have to be known; and 3) a minimal amount of sample is required. However, in the case of salts, excess base or acid is counted as an impurity.

DSC calculations of drug purity were used to assess the quality of progesterone and lipoic acid, and to define specifications for the drugs (13). The enantiomeric purity of (–)ephedrinium 2-naphthalenesulphonate has also been determined using DSC (14).

Crystallization

Crystallization can occur on cooling from the melt and/or heating above the glass transition temperature of amorphous materials. The temperature at which this occurs is the crystallization temperature, T_c . Through DSC, crystallization is observed as an exothermic transition with an enthalpy of crystallization, ΔH_c (Fig. 2). The energy released when the molecules, atoms, or ions organize into a 3D solid state is related to the crystal lattice energy. Some compounds can crystallize into different molecular arrangements called polymorphs, discussed later.

Fig. 3 DSC scan of drug substance divided into segments, A_i , for purity calculations of a compound of total enthalpy or area, A_T (inset, only a few segments are shown). The van't Hoff plot of the temperature of each segment as a function of $1/F = 1/(A_i/A_T)$, and with correction (straight line) for determination of purity of the drug substance.

Quantification of Crystallinity

The crystallinity of drugs and excipients before and after formulation processing can be determined using calorimetry. In some cases, crystalline compounds can convert during pharmaceutical processing to the amorphous form, which is a thermodynamically less stable form. Amorphous compounds consist of nonordered molecules (see the section on *Glass Transition*). This can have important implications for the chemical and physical stability of the formulations. The effect of grinding on the crystallinity of cefixime trihydrate was evaluated using DSC and other thermal techniques. The dehydration temperature of the ground sample decreased linearly with decreasing crystallinity (15).

An exothermic transition can sometimes be observed by DSC on crystallization of the amorphous form. This can be used to quantify the amorphous content of crystalline drugs. A calibration curve that consists of a plot of the enthalpy of crystallization as a function of crystalline content was used to determine if the lyophilized MK-0591 drug substance was completely amorphous or contained some crystalline compound (16).

Polymorphism

Polymorphs are crystalline compounds of the same molecular structure that have a different arrangement of molecules in the unit cell.^a Polymorphs have the same chemical composition but have unique cell parameters. Therefore, polymorphs can have very different melting temperatures, densities, solubilities, chemical and physical stabilities, dissolution rates, and bioavailabilities (17).

Polymorphs are either enantiotropic or monotropic. Enantiotropic polymorphs have a thermodynamic conversion temperature where one form is more stable above this temperature while the other is more stable below. Processing the least stable form, dissolution/recrystallization, and certain storage conditions might cause enantiotropic polymorphs to later convert (5). If there is no conversion temperature below the melting temperatures of the polymorphic pair, then the different crystal forms are monotropic. That is, there is only one crystal form that is thermodynamically stable at all temperatures and pressures. Calorimetry can be used to determine which polymorph is the more stable form. DSC can provide accurate unambiguous melting temperatures and enthalpies of fusion. Based on the melting temperature and the enthalpy of fusion, the relative thermodynamic stability of the polymorphic

pair can be determined [e.g., using the Heat of Fusion Rule (5)].

DSC and complimentary thermal techniques, such as temperature X-Ray powder diffraction, were used to determine the thermodynamic relationship of the six anhydrous polymorphs of tetracaine hydrochloride (17). The phase diagram of the polymorphic conversion of diflunisal in polyethylene glycol (PEG) 4000 solid dispersions was obtained as a function of polymer content (18).

Heat Capacity

Accurate heat capacity, C_p , measurements may be obtained by DSC under strict experimental conditions, which include the use of calibration standards of known heat capacity, such as sapphire, slow accurate heating rates (0.5–2.0 K/min), and similar sample and reference pan weights (19, 20). MDSC or DDSC also have been used to determine the heat capacity of several pharmaceutical materials (6, 21).

Glass Transition

By the use of various pharmaceutical manufacturing processes, (e.g., lyophilization or comminution techniques), drugs or excipients may be made amorphous. Amorphous compounds are defined by their lack of long-range molecular order and structural periodicity. Their high energy state is of great interest to the pharmaceutical industry as it can lead to fast dissolution rates and increased bioavailabilities. However, amorphous compounds are thermodynamically unstable, although depending on their glass transition temperature, they may be kinetically stable for extended times. Amorphous compounds are characterized by a glass transition, which by DSC is seen as an increase in heat capacity change (Fig. 2):

$$\Delta C_p = C_{p_{\text{liq}}} - C_{p_{\text{glass}}} \quad (10)$$

where $C_{p_{\text{liq}}}$ is the heat capacity of the liquid, and $C_{p_{\text{glass}}}$ is the heat capacity of the glassy phase. The glass transition temperature is measured either at its onset or midpoint as shown in Fig. 4. Structural relaxation can occur due to the restricted but finite mobility of the molecules below the glass transition. This gradual volume or enthalpy change is observed by DSC as an endothermic peak superimposed on the glass transition (Fig. 4), and this may lead to difficulties in interpretation of the transition. Modulated DSC can sometimes be used to separate the enthalpic overshoot from the glass transition temperature (5).

^aSee *Polymorphism: Pharmaceutical Aspects*, page 2249.

Fig. 4 (a) DSC scan of the glass transition temperature of a miscible blend of a MK-0591 with 10% PVP, showing the onset, midpoint, and offset glass transition temperatures. (b) DSC scan of the glass transition of sucrose with the enthalpic relaxation endotherm and enthalpy (ΔH_R). (From Ref. 5.)

Defining the glass transition temperature is important to the development of stable amorphous pharmaceutical materials. A leukotriene biosynthesis inhibitor, MK-0591, has been shown to be kinetically stable in the amorphous phase at normal storage temperatures if protected from moisture, due to its elevated glass transition temperature of 125°C (16). In lyophilized systems, a high T_g' , defined as the apparent glass transition temperature and observed as the change of the heat capacity of the lyophilized formulations, is important to define the stability of such formulations (22–24). MDSC has been used to select optimal freeze-drying conditions to avoid cake collapse (25, 26).

The glass transition temperature of amorphous multicomponent mixtures can be used to determine the miscibility of the components. If the mixture is miscible, then a single glass transition temperature is usually obtained. Various equations can be used to predict the glass transition temperature of miscible mixtures. Examples include the Gordon-Taylor equation (Eq. 11) or the Fox-Flory equation (Eq. 12).

$$T_{g\text{ mix}} = [w_1 T_{g1} + K w_2 T_{g2}] / (w_1 + K w_2); \quad (11)$$

$$K = \rho_1 T_{g1} / \rho_2 T_{g2}$$

$$1/T_{g\text{ mix}} = 1/T_{g1} + 1/T_{g2} \quad (12)$$

where ρ_1 and ρ_2 are the densities of the two components and T_{g1} and T_{g2} are their respective glass transition temperatures (27).

Temperature Dependence of Molecular Motions in Amorphous Materials

A critical attribute that dictates the stability and performance of any amorphous material is the manner in which its rate of molecular motions (τ) varies with changing temperature (T) (i.e., $d\tau/dT$). At temperatures which are approximately 0–100 K above the calorimetric glass transition temperature (T_g), this property is known as the *fragility* of the material (27). Several workers have suggested that $d\tau/dT$ below T_g (in the nonequilibrium glassy state) is the most appropriate descriptor of amorphous pharmaceutical materials since this is the normal state for the storage and processing of such systems (27, 28). A simple graphical plot of τ versus T can be constructed at temperatures below T_g from the results of enthalpy relaxation experiments. These measurements can be performed using either a conventional DSC or microcalorimeter (28, 29). Alternate calorimetric methods of estimating $d\tau/dT$ at T_g have been described in the literature (30), but the applicability of these methods to pharmaceutical materials has not yet been clearly demonstrated (31).

Degradation, Decomposition, Stability Determinations, and Drug-Excipient Compatibility

The degradation, decomposition, and stability of drugs or formulations can be determined by DSC or microcalorimetry. The advantages of the techniques are their speed of measurement and the small amounts of sample required.

At times, interpretation of the results can be difficult, particularly when simultaneous reactions occur. Decomposition kinetics are generally determined using the Arrhenius equation. The samples are stored at elevated temperatures for known periods of time and analyzed by DSC. Alternatively, they can be held isothermally in the DSC at different temperatures, followed by scanning at heating rates sufficiently fast to avoid additional decomposition. A rate constant is calculated for each storage condition by plotting the logarithms of the areas of the transitions (e.g., the decomposition endotherm, etc.) as a function of time. The natural logarithm of the reaction rates, k , are then plotted as a function of $1/T$ as per the Arrhenius equation.

$$k = Ze^{-(E_a/RT)}; \quad \ln k = \ln Z - E_a/RT \quad (13)$$

where Z is the Arrhenius frequency or pre-exponential factor, E_a is the Arrhenius activation energy (J/mol) for the reaction, and R is the gas constant. The activation energy and pre-exponential factor are assumed to be constant and independent of temperature.

Alternatively, the reaction peak maxima may be determined at different heating rates (φ) and used to calculate the activation energy, assuming first order kinetics.

$$E_a = -2.19 T \frac{d \log \varphi}{d(1/T)} \quad (14)$$

The energy of activation is obtained from the slope of the log of the heating rate (φ) as a function of $1/T$ (31). It is assumed that only one reaction occurs during the transition and that the peak maximum represents a point of constant conversion for each heating rate. The method cannot be used with compounds that decompose on melting or undergo isomerizations at the reaction temperature or any other simultaneous reaction (32). Some modification of DSC may be needed to determine the degradation kinetics of compounds under different environmental conditions.

DSC is often used for the rapid screening of excipients for drug-excipient compatibility studies. Certain assumptions have to be made, which include that the thermal properties of these mixtures are the sum of the individual components when there are no interactions between the components. The method does not take into consideration: 1) effects due to thermal conductivity (thermal lag effects); 2) mixing effects that can lower the purity of each component resulting in slightly broader, lower melting temperatures; or 3) sample geometry effects that result in variations in peak shapes and peak temperatures. In addition, reduction in enthalpies of fusion can occur as a result of the solubilization of the drug in molten excipients. This latter phenomenon can be used in

part to determine the solubility in different molten excipients (5, 33).

Interactions with Water/Solvents, Hydrates

Water can have a significant impact on the physical and chemical stability of drugs. Water may be present as part of the crystalline lattice (hydrate), or it may be on the surface ("free") or more tightly incorporated ("bound"). The evaluation of the type of water present in a pharmaceutical material has been determined using subambient DSC (thermoporosimetry), such as in the case of magnesium stearate hydrates (34, 35), as well as thermogravimetric techniques. Free or surface water can crystallize and the melting enthalpy of this free water can be used to calculate the surface water content of compounds from the melting enthalpy of pure water (36). The state of water in HPMC gels with and without drugs, such as propranolol hydrochloride or diclofenac, was determined in this way by DSC (37).

MICROCALORIMETRY

Microcalorimetry is used to monitor thermal changes associated with physical and/or chemical events that do not require heating or cooling for their initiation. Such events include dissolution, precipitation, reaction, and crystallization. In a typical microcalorimetry experiment, these events are "triggered" in a controlled manner by mixing two pre-equilibrated and separate phases (e.g., water vapor and amorphous drug, solvent and crystalline drug, or protein and carbohydrate solutions). Microcalorimetry techniques are sometimes referred to by the processes that are monitored (e.g., immersion calorimetry, solution calorimetry, titration calorimetry, etc.) (38). Differential scanning calorimeters may be operated in isothermal mode; however, for highly accurate and reliable isothermal measurements, specially designed microcalorimeters are required.

Thermodynamics

Solution microcalorimetry may be used to determine the free energy of dissolution of a solid compound, which is particularly important in pharmaceutical research for dissolution studies and in the determination of the relative thermodynamic stability of polymorphs (38). The change in the Gibbs–Helmholtz free energy, ΔG_{sol} , on dissolution is

$$\Delta G_{\text{sol}} = -RT \ln K_{\text{eq}} \quad (15)$$

where T is the temperature (Kelvin, K), R is the gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$), and K_{eq} is the equilibrium constant for the change of the compound from the solid state to the dissolved liquid state. The equilibrium constant can be determined, at low concentrations, from the ratio of the concentration of the compound in the solution, or its solubility, to that in the solid state (where by definition, $[C]_{\text{solid}} = 1$).

$$K_{\text{eq}} = [C]_{\text{soln}}/[C]_{\text{solid}} = [C]_{\text{soln}} \quad (16)$$

The ΔH_{sol} is the enthalpy change that occurs on dissolution of one mole of compound in a solvent. The solution microcalorimeter may be used to obtain the enthalpy of solution directly. The change of free energy can be calculated from the concentration using the enthalpy obtained. The change in the entropy of solution ΔS_{soln} can then be determined from the Gibbs–Helmholtz equation (2, 3).

Alternatively, the change in free energy of solution ΔG_{soln} can be calculated from the van't Hoff equation:

$$\delta(\Delta G_{\text{soln}}/T)/\delta T = -\Delta H/T^2 \quad (17)$$

It may be more accurate to obtain the enthalpy directly from microcalorimetry (39).

Instrumentation

The simplest type of nonscanning calorimeter is the isoperibol instrument (Fig. 5). In this type of calorimeter, a constant environment is maintained inside an insulated reaction vessel. Typically, a silvered dewar is used, and the interacting components (e.g., solvent and solute) are held in sub-containers. Liquid phases are usually stirred and the temperature is accurately recorded using a thermometer or thermocouple. At the start of the experiment, the reaction vessel is allowed to reach a steady state, and a baseline temperature or temperature drift is recorded. The interaction of interest is then initiated by permitting the two components to mix, and the resulting temperature increase from baseline is recorded. The system is calibrated by monitoring a standard reaction (e.g., neutralization of hydrochloric acid) or by applying a controlled amount of electrical energy via a heating coil. Isoperibol calorimeters can be easily constructed from their individual components, and several different instruments are commercially available at a modest cost.

Due to the high degree of accuracy and sensitivity that is required for pharmaceutical analysis, more sophisticated microcalorimeters are frequently used for studying

Fig. 5 Schematic diagram of an isoperibol calorimeter (top) and a thermal activity monitor (bottom).

pharmaceutical systems. An example of such an instrument is the Thermal Activity Monitor (TAM) manufactured by Thermometrics (Sweden). In this instrument, twin sample cells are used (one for the sample and one for a reference) to achieve greater signal stability and to minimize the effects of spurious thermal fluctuations (Fig. 5, bottom). The cells are housed in a constant temperature environment maintained via a sophisticated heater and water jacket system. Minor changes in sample heat flow are detected with relative ease using this

arrangement. The TAM is calibrated electrically, and the commercially available sample configurations allow the mixing of solids, liquids, and gases in various proportions. Controlled gas and liquid flow rates, and changing sample environments (e.g., relative humidities) can also be achieved with appropriate accessories. A major practical advantage of this type of calorimeter when compared with less sophisticated instruments is the small sample size requirement of only a few tens or hundreds of milligrams per determination. The TAM microcalorimeter has been used for detection and monitoring of crystallization events, sorption and desorption of organic and inorganic vapors, chemical reactions (drug degradation and drug interactions with excipients), molecular motions in amorphous pharmaceutical materials, ligand binding phenomena, microbiological growth, and the determination of solid heat capacities.

Sample Preparation and Calibration

Microcalorimeters are usually operated in a similar way irrespective of the source of the energy change that is being monitored. Specimens are pre-equilibrated at the desired measuring temperature for several hours and then introduced into the calorimeter chamber. After a short delay, the external stimulus is applied to trigger the event of interest, and then the energy that is liberated or consumed is measured. The reaction is isolated from the environment by a jacket, which serves as a thermal shield to minimize the absorption and emission of radiant heat (Fig. 5). Calibration of microcalorimeters is usually achieved by direct heating using an electric heating element (as mentioned previously). Extreme care is required to achieve consistent sample preparation and to maintain constant experimental procedures since the interpretation of results can be confused easily by experimental artifacts. Simultaneous thermal events of opposite sign (exothermic and endothermic) are quite common and may often confound the interpretation of data. In all experiments, an appropriate thermal reference is required since the energy changes that are measured are simply energy changes relative to the reference specimen. Common references include an empty sample container, or a sample container filled with an inert material which has a similar heat capacity and mass to the sample.

Definitions and Applications of Microcalorimetry

Microcalorimeters have found widespread use in the pharmaceutical sciences in recent years for applications as diverse as determining the degradation rate of drugs,

estimating the strength of binding between proteins and receptor sites, and monitoring metabolic processes in microorganisms.

Hollenbeck used immersional calorimetry to investigate interactions between microcrystalline cellulose and water (39). Interactions of hydroxypropyl methylcellulose and cholestyramine with water also have been investigated by microcalorimetry (40, 41). In addition, the desorption of water from theophylline monohydrate has been investigated using microcalorimetric approaches (42). The properties of surfactants and surface active drugs in solution were studied by Attwood et al. (43) using calorimetry, while titration microcalorimetry has been utilized to elucidate the nature of specific interactions in several pharmaceutical polymer-surfactants systems (44, 45). A more unusual pharmaceutical use of microcalorimetry is to study energetic changes that occur during tablet compaction (46, 47). The compression calorimeter is a custom-made research instrument that appears to have many potential applications for the pharmaceutical scientist.

Microcalorimetry has proven to be a particularly useful tool to detect different levels of disorder in pharmaceutical materials (48). Pikal et al. used a solution calorimetry approach to measure differences in the crystallinity of a wide range of antibiotic samples (49). Gao and Rytting demonstrated the validity of this approach for a wider range of materials (50). Other workers have used elevated vapor pressures to trigger crystallization of disordered materials in the calorimeter and have been able to use the measured energy output to directly quantify the levels of disorder crystallinity in their samples (51).

Stability studies using microcalorimetry are widely reported in the literature (38, 52–54). Some authors have monitored exothermic degradation reactions over several days or weeks and have projected the degradation extent and rate over the shelf-life of the drug or drug product. Other authors have used microcalorimetry to monitor relaxation of amorphous pharmaceutical materials and have then calculated relaxation time constants from these data for use in shelf life predictions (29). The use of microcalorimetry for preformulation stability screening of a drug with potentially reactive excipients has also been described (55).

REGULATORY CONSIDERATIONS

Calorimetric methods are infrequently used for routine quality control purposes because of their nonspecific nature and relatively slow speed. However, data from calorimetry experiments are commonly presented in applications for

new product licenses and in support of patent applications. To ensure the integrity of all calorimetry data, normal procedures for good laboratory practices, standard operating procedures, appropriate calibration methods, and regular instrument servicing are necessary. The use of DSC for the measurement of transition temperatures and sample purity is described in the United States Pharmacopoeia, and standard procedures for DSC analyses are also suggested by the ASTM (100 Barr Harbor Dr., West Conshohocken, Pennsylvania 19428).

INTRODUCTION

Soft gelatin capsules (also referred to as soft elastic gelatin capsules, Liqui-gels®, or softgels) are a unique drug delivery system that can provide distinct advantages over traditional dosage forms such as tablets, hard-shell capsules, and liquids. However, due to economic, technological, and patent constraints, there are relatively few manufacturers of softgels in the world (1).

Some of the major advantages of softgels include:

- improved bioavailability (increased drug absorption (2))
- speed of product development
- enhanced drug stability (protection against oxidation, photodegradation, and hydrolysis in lipophilic systems)
- superior patient compliance/consumer preference (ease of swallowing, appealing appearance, absence of objectionable taste, and convenience) and pharmaceutical elegance
- excellent dose uniformity (less than $\pm 1\%$ for solution fills; $\pm 1-3\%$ for suspension fills)
- better tamper evidence (tampering leads to puncturing and visible leakage)
- safer handling of highly potent or cytotoxic drug compounds
- product differentiation (through selection of novel shapes, colors, and sizes)
- excellent product life-cycle management.

In comparison, the disadvantages of softgels are relatively few. These include:

- specialized manufacturing equipment requirements
- higher cost for manufacturing as compared to tablets
- limited availability of technical experts

In surveys comparing various pharmaceutical dosage forms, softgels are rated as a high tech dosage form with strong customer preference. They are formed, filled, and sealed in a single operation. Once production for a specific

product begins, the manufacturing process normally proceeds 24 h per day until the lot of product is completed. This results in a manufacturing environment that operates around the clock, 7 days a week.

The standard softgel shapes for oral pharmaceutical products are oval, oblong, and round, though softgels can be easily manufactured in any shape. A recent survey has shown that smaller sized softgels are preferred within each shape category, with oval being the most popular shape.

DESCRIPTION

The softgel (Fig. 1) is a hermetically-sealed, one-piece capsule with a liquid or semisolid fill. The softgel consists of two major components, the gelatin shell and the fill (Fig. 2). In the finished product, the gelatin shell is primarily composed of gelatin, plasticizer, and water. The fill materials can include a wide variety of vehicles and can be either a solution or a suspension. Softgels may be coated with suitable enteric coating agents, such as cellulose acetate phthalate, to obtain enteric release of encapsulated material.

Because of their special properties and advantages, softgels are used extensively in many pharmaceutical, cosmetic, and nutritional products. The primary pharmaceutical applications include oral dosage forms, chewable softgels, suppositories, and topical products. The size of a softgel represents its nominal capacity in minims (1 cc = 16.23 minims). For example, an 11 oblong softgel can be filled with 8.5–11.0 minims of fill formulation.

FORMULATION DEVELOPMENT

Having selected the softgel dosage formulation of a drug, the desired performance characteristics will influence the

Fig. 1 Examples of softgels.

nature of the development of that formulation. The first consideration in this process is whether the softgel should be transparent, containing a solution of drug, or opaque, containing a drug suspension. Next, it must be determined whether the formulation is intended to provide bioequivalence with another product or to have enhanced performance *in vivo*; for example, faster or more complete absorption. This section will discuss the formulation principles of softgels, including gelatin shell and fill formulations.

Gelatin Shell Formulation

Typical softgel shells consist of gelatin, plasticizer, water, and materials that impart the desired appearance (colorants and/or opacifiers) and, on occasion, flavors and/or preservatives. A description of the functions, types, and amounts of materials most often used in manufacturing softgel shell formulations is detailed in the following paragraphs.

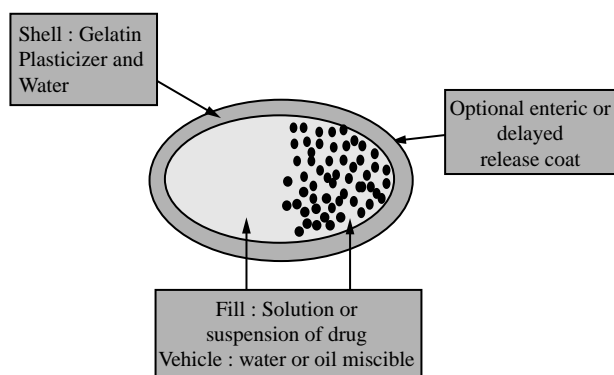

Fig. 2 Softgel components.

Gelatin

Gelatin provides the structural support for the shell of the softgel. It is typically 40–50% of the wet gel formulation and can be either Type A (acid processed) or Type B (alkali processed). The selection for the type of gelatin for a particular softgel formulation is based on compatibility with the other ingredients (both active and inactive) within the softgel. The steps involved in the gelatin manufacturing process include extraction, neutralization, drying, and grinding (3). The physicochemical properties of gelatin are largely controlled by the source of collagen, extraction method, pH, thermal history, and electrolyte content.

Plasticizers

Plasticizers are used to make the softgel shell elastic and pliable. The ratio of plasticizer to gelatin determines the hardness of the shell, assuming there is no effect from the fill. Plasticizers generally account for 20–30% of the wet gel formulation and are commonly glycerin, sorbitol, or propylene glycol, either individually or in combination. Several proprietary blends of sugar mixtures with sorbitol anhydrides can also be used and are available from excipient suppliers (4, 5). The amount and choice of the plasticizer help to determine the hardness of the final product, and may also affect the dissolution or disintegration of the softgel, as well as its physical and chemical stability. Plasticizers are selected on the basis of their compatibility with the fill formulation, processing (drying) time, and desired properties of the final softgels, including hardness, appearance, handling characteristics, stability, and even the geographical location in which the product will be sold.

Water

Water usually accounts for 30–40% of the wet gel formulation and is critical to ensure proper processing during gel preparation and softgel encapsulation. Following encapsulation, excess water is removed from the softgels through controlled drying, leaving the equilibrium water content typically at less than 10%.

Colorants/Opacifiers

Colorants and opacifiers are typically used at low concentrations in the wet gel formulation. A wide range of colorants such as FD&C and D&C water-soluble dyes, certified lakes, pigments, and vegetable colors have been incorporated into gelatin shells alone or in combination to produce the desired color, tint, or hue for product identification. A general rule in color selection is that the color of the capsule shell should be similar to or darker than the fill material.

An opacifier is sometimes added to the gelatin shell to obtain an opaque shell for suspension fills or to protect light sensitive fill ingredients. Titanium dioxide is the most commonly used opacifier. Flavors such as ethyl vanillin and essential oils are sometimes included in the capsule shell to impart desirable odors or flavors or to offset odoriferous materials that may be contained within the softgel itself.

Fill Formulation

Because of the migration of components (water, plasticizers, drugs, etc.) within the softgel both during and following encapsulation, formulation of the fill material must be conducted concurrently with formulation of the shell for maximum product quality. Without this simultaneous development, it is not uncommon for problems to arise.

The viscosity of fills can range from mobile liquids to thick suspensions or pastes. The fill material in a soft gelatin capsule can be a liquid, a combination of miscible liquids, a solution of a solid(s) in a liquid(s), or a suspension. These formulations are designed to produce the smallest possible capsule consistent with acceptable chemical and physical stability, therapeutic effectiveness, and production efficiency.

The large groups of liquids that can be encapsulated into softgels fall into one of two categories: water-miscible liquids and water-immiscible liquids (6).

Water-miscible liquids include polyethylene glycols and nonionic surfactants, such as the polysorbates. Low molecular weight grades of polyethylene glycol (e.g., PEG 400) are used most commonly since they remain liquid at ambient temperatures. Small amounts (up to 5–10%) of other water-miscible liquids, such as propylene glycol, ethanol, and glycerin, can also be used.

Water-immiscible liquids include vegetable and aromatic oils, aliphatic, aromatic and chlorinated hydrocarbons, ethers, esters, high molecular weight organic acids, and some alcohols.

Liquids that are likely to cause problems following encapsulation are low molecular weight water-soluble and volatile organic compounds, such as some alcohols, acids, ketones, and esters; water (above 5%); emulsions (whether oil in water or water in oil); liquids with extremes of pH; and aldehydes.

Drugs that are not sufficiently soluble in the solvent or combinations of solvents can be formulated into suspensions and encapsulated. The particle size of insoluble drugs should be 80 mesh or finer for maximum suspension homogeneity and capsulation equipment requirements. Examples of suspending agents include paraffin wax, beeswax, and hydrogenated vegetable oil for oily vehicles,

and solid glycol esters (such as higher molecular weight PEG) for nonoily vehicles. Surfactants, such as polysorbates, are often added to the dispersion to promote wetting of the ingredients and/or dispersion of the fill *in vivo*.

In general, many different materials may be encapsulated; however, limitations do exist for some compounds due to high solubility in water and/or inherent chemical reactivity and the resultant effect on the shell. These compounds include strong acids and alkalis and their salts, as well as ammonium salts. Some compounds, such as aldehydes, can react with gelatin, causing crosslinking and resulting in a product that lacks bioavailability. In addition, any substance (such as aspirin) that is unstable in the presence of moisture may also exhibit unacceptable chemical stability in softgels.

PRODUCT DEVELOPMENT

This section will discuss the rationale of softgel product development, including solubility screening, gel compatibility, process development, and trial batch manufacture, concluding with a review of the manufacturing process and specialized formulation approaches to enhance pharmacokinetic performance.

The flow diagram in (Fig. 3) details the activities normally undertaken in the development of a softgel. The major steps involved are described in the following paragraphs.

The first step in developing a solution containing softgel is to determine the solubility of the drug in a range of pharmaceutically acceptable solvents. After the solubilities are measured, the solvents are then selected on the basis of their regulatory acceptability and known compatibility with softgel dosage forms. The types of excipient typically include:

- hydrophilic solvents
- lipophilic materials
- hydrophilic surfactants
- lipophilic surfactant
- co-solvents.

Solvents that provide adequate solubility of the drug can be selected, though it may be necessary to combine them to achieve the desired *in vitro* or *in vivo* characteristics and to ensure good physical stability. In addition to characterizing the *in vitro* and *in vivo* performance of the preliminary formulation, it is important to evaluate the drug solubility in the mixtures for the following conditions:

- physical stability under accelerated conditions
- chemical stability under accelerated conditions
- excipient compatibility.

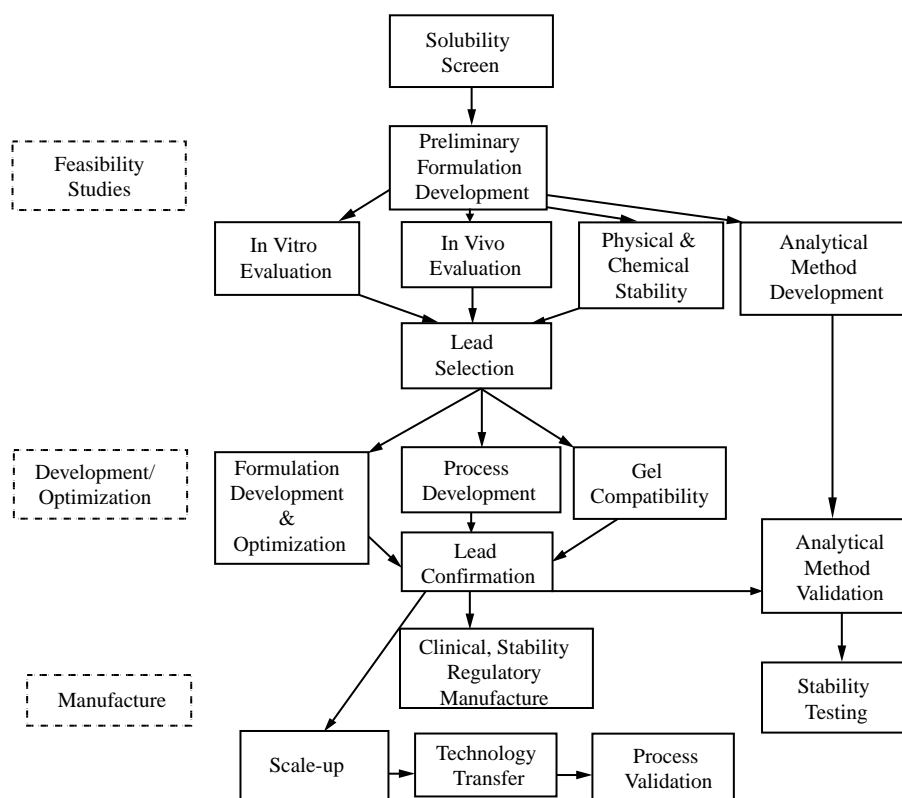

Fig. 3 Typical softgel development flow diagram.

For softgels containing suspension fills, the solubility of the drug in a range of pharmaceutically acceptable solvents is also measured and excipients in which the drug shows little or no solubility are then selected. These formulations generally require viscosity enhancers in order to provide adequate suspending characteristics for the drug during processing. This is vital in maintaining drug homogeneity during manufacture. The type and level of viscosity enhancer is optimized to provide the best manufacturability.

Gel Compatibility

Thorough gel compatibility testing between the fill and shell formulation is an important part of the development process. A variety of problems may result if the fill is not well matched to the proper shell formulation. These may be observed either immediately after encapsulation or after prolonged storage.

Process Development/Trial Manufacture

Having identified potential fill and shell formulations on the laboratory scale, a suitable manufacturing process that

will enable successful preparation of the trial batch materials required for regulatory and clinical studies must be developed. Such process development includes investigating several processing parameters, such as the order of addition, temperature, mixing condition, and selection of equipment.

Formulations selected for stability and clinical evaluation will be prepared as trial (pilot) batches. During manufacture, the process and product will be evaluated to provide valuable information for later process ranging and validation studies. For example, the fill moisture and hardness of the capsules during the drying stages will be monitored to optimize the drying process and resulting product stability. Fig. 4 shows the drying profile of a softgel product. Note that the reduction in fill moisture is accompanied by an increase in capsule hardness.

METHOD OF MANUFACTURE

As early as the 1830s, softgels were used as a method of drug delivery. Early manufacturing included both a hand-dipping method and a plate-press method. The hand-dipping

Fig. 4 Typical drying profile.

method created individual empty softgel shells that were subsequently filled with a syringe or dropper. The plate-press method was a batch process that involved pressing two sheets of wet gelatin together between two molds. The molds provided depressions in the gelatin sheet into which active fill was then placed. A second gelatin sheet was laid

over the first and both were pressed together with fill material sandwiched between. The pressure of the plate dies sealed the top and bottom sheets of gelatin together and cut out the individual softgels for subsequent drying.

Almost every softgel on the market today is made using the rotary die process patented by Scherer in 1933 (7). The equipment and manufacturing process has improved dramatically over the years, but the underlying manufacturing principle remains essentially unchanged. In this method, two independent processes take place, often simultaneously, yielding two different materials, the gel mass and the fill material. Both are united in the encapsulation process that produces wet softgels.

The wet gel mass is manufactured by mixing together and melting, under vacuum, the gelatin shell ingredients (gelatin, plasticizer, water, colorants and sometimes opacifiers, flavors, and preservatives). At the encapsulation machine (Fig. 5), molten gel mass flows through heated transfer tubes and is cast onto chilled drums, forming two separate ribbons, each approximately 6 in. wide. The thickness of the ribbons (usually 0.02–0.04 in.) is carefully controlled and checked periodically throughout manufacture. The gel ribbons traverse through rollers that provide proper alignment of the ribbons and apply lubricant to both surfaces of the ribbons. Each gel ribbon forms one half of the softgel. Two-toned softgels are made using two different colored gel ribbons.

Active fill materials are manufactured in a process separate from the gel mass manufacture. The viscosity of

Fig. 5 Encapsulation equipment.

Fig. 6 Newly formed softgels.

all fills and the particle size of suspended materials are important parameters established during development and controlled throughout manufacture.

Softgels are formed during the encapsulation part of the process, using the two gel ribbons and the fill material. Lubricated gel ribbons are fed between a pair of counter-rotating dies, the surface of which contains matching pockets of appropriate size and shape that serve as molds for forming the softgels. The die pockets also seal both sides of the softgel and cut the formed softgel away from the residual gel ribbon. Fig. 6 shows softgels immediately following encapsulation as they are being separated from the ribbons. The softgels are then conveyed to a tumble dryer to initiate drying.

Situated between the ribbons and rotating dies is the wedge as shown in Figs. 7 and 8. The wedge serves three separate functions during the encapsulation process. First, it heats the gel ribbons close to the gel-sol transition temperature to ensure that melting (welding) of the two gel ribbons occurs when the ribbons are pressed together between the dies. Second, the wedge is part of the system that distributes the fill material from a positive displacement pump to each of the die pockets. Finally, the wedge, in conjunction with the lubricant, provides a sealing surface against the ribbons to eliminate air and allows a seal to be formed between the shell and fill material without the introduction of air into the product.

In order to properly manufacture the gel mass and form the gel ribbons, the gel mass formulation contains excess water. Following encapsulation, softgels must be dried to obtain a final product that will be durable enough to withstand subsequent processing, packaging, and shipping, and possess good long term physical stability. Drying occurs in two stages. Initial drying takes place in a rotating basket dryer that tumbles the softgels in temperature and humidity controlled air. This removes approximately half of the excess water. The balance of the excess water is removed during the secondary drying stage, when the softgels are spread in a single layer on shallow trays. The trays are designed and stacked to allow air to pass through the rack and around the softgels (Fig. 9). Secondary drying proceeds under controlled conditions of temperature and humidity until the appropriate level of hardness or fill moisture is achieved. Complete drying can

Fig. 7 Softgel encapsulation process.

Fig. 8 Close-up of die-wedge equipment.

take from 3 days to 3 weeks depending on shell and fill formulations and the size of the softgel.

Once the softgels have reached the desired drying endpoint, they are placed into bulk holding containers to prevent further drying. At this point, several additional operations may be performed, including washing, printing, inspecting, and packaging.

THERAPEUTIC PERFORMANCE

The pharmacokinetic performance of drugs can be enhanced by softgel dosage forms, the exact formulation of which depends on the desired pharmacokinetic improvement. The two most common requirements for

Fig. 9 Tray drying of softgels in controlled drying tunnels.

this formulation are faster and more complete absorption. In both cases, the ideal situation is for the drug to be dosed in solution and formulated to remain in solution after dispersion in gastrointestinal media, possibly as a nanoemulsion. Formulation of nanoemulsion preconcentrates for softgel encapsulation requires the drug to be in solution in a mixture of oils, surfactants, cosurfactants, and possibly cosolvents.

Rate of Absorption

Noteworthy advances recently have been made in the development of softgel formulations to address particular performance issues in vivo. These include presentation of the drug to the gastrointestinal tract in a solution from which the drug can be absorbed significantly faster than that from a solid oral dosage form, which may be rate-limited by the need for disintegration followed by drug dissolution. With the solution-softgel approach, the shell ruptures within minutes to release the drug solution, usually in a hydrophilic or highly dispersing vehicle that aids the rate of absorption. This can be a valuable attribute for treatments such as migraine or acute pain, or where there is a limited absorption window in the gastrointestinal tract. Fig. 10 compares the absorption rates between a solution softgel formulation and a tablet of ibuprofen (8). The data are based on a pharmacokinetic comparison of 400 mg ibuprofen in 12 human volunteers.

Increased Bioavailability

In addition to increasing the rate of absorption, softgels may also improve the extent of absorption. This can be particularly effective for large hydrophobic drugs.

Fig. 10 Comparison of absorption rates of ibuprofen from softgel and tablet.

Fig. 11 Comparison of nanoemulsion softgel to a drug suspension capsule.

Recently, the protease inhibitor saquinavir has been relaunched in a patented solution–softgel formulation, providing approximately three times the bioavailability as the original hard-shell formulation (9).

In some cases, drugs may be solubilized in vehicles capable of spontaneously producing a microemulsion or nanoemulsion on contact with gastrointestinal fluids. This particular vehicle consists of oils and surfactants in appropriate proportions which, on contact with aqueous fluids, produce an emulsion preferably with an average droplet size less than 100 nm. The solubility of the drug should be maintained as long as possible, delivering solubilized drug directly to the enterocyte membrane. It may even be possible to utilize the body's own systems for oil digestion to produce micelles containing solubilized drug. Fig. 11 depicts the enhancement in plasma levels achieved in 12 human volunteers when a nanoemulsion softgel was used to dose a hydrophobic drug as compared

to a capsule containing a suspension of micronized drug particles (9).

Decreased Plasma Variability

High variability in drug plasma levels is a common characteristic of drugs with limited bioavailability. By dosing the drug optimally in solution, the variability of such drug plasma levels can often be reduced. Cyclosporin benefits from such an approach (10). Fig. 12 depicts the administration of a 10 mg/kg dose of Cyclosporin A (Sandimmune®) softgel solution formulation in eight human volunteers (11). Fig. 13 depicts the administration of a 10 mg/kg dose of Cyclosporin A (Neoral®) microemulsion preconcentrate softgel formulation in eight fasting human volunteers (11).

PRODUCT QUALITY CONSIDERATIONS

Ingredient Specifications

Numerous specifications and control measures are employed to determine final product quality, the first of which is ensuring adequate quality of excipients and active ingredients. Excipient testing ensures compliance with compendial specifications, as well as specifications determined during development of the fill material and/or shell formulation. Among these are limiting values for trace impurities, especially peroxides, aldehydes, some metals, and ionic salts. Presence of these impurities can result in gelatin crosslinking and possible dissolution

Fig. 12 Cyclosporine A (Sandimmune®) softgel formulation.

Fig. 13 Cyclosporine A (Neoral[®]) microemulsion preconcentrate softgel formulation.

problems or in undesired changes in the product appearance over time.

Since gelatin is the key ingredient for the shell and is present in larger quantities than other excipients, it is important to ensure that the gelatin meets not only current USP specifications, but the additional controls of particle size, viscosity, and bloom strength, all of which are significant for manufacturing process as well as final product stability. Other specifications, such as the quantity of certain ionic materials, are necessary to ensure stable product appearance during storage. Furthermore, it is essential to specify or limit other gelatin properties, such as color or even the source of the gelatin (bovine, porcine, bone, hide), depending on the formulation and intended market of the final product.

In-Process Testing

Several tests are conducted on a regular basis throughout the encapsulation portion of the softgel manufacturing process. These include weight determinations for both the fill material and the shell, and measurements of the thickness of the seals of the softgels themselves.

Fill moisture and/or hardness measurements are performed during the drying process, the results of which are used to determine the drying endpoint for each lot. Specifications for fill weight, shell weight, seam thickness, and drying endpoints are based on the softgel size, amount and type of fill, and the results obtained during previous process development studies.

Final Product Testing

Once the softgels have completed all required processing steps, the lot is inspected and sampled for final product

release testing. Tests required for final product release are dependent on regulatory requirements for the product and usually include microbiological testing, assay and identity of actives, physical appearance, fill weight, dissolution or disintegration, and dosage uniformity.

RECENT ADVANCES IN NEW TECHNOLOGY

Recent advances in the development of softgel formulations and manufacturing have lead to exciting improvements, including the capability of imprinting the product logo directly on the wet gelatin ribbon prior to encapsulation, the ability to encapsulate small quantities of softgels in the laboratory setting for early stability or quick in vivo evaluations, and the ability to encapsulate microspheres (controlled or immediate release) suspended in the fill.

TRENDS IN PATENT ACTIVITY

A review of the United States patent activity over the past decade reveals some interesting trends within the softgel technology arena. While the review is limited to U.S. patents, it most likely represents the patent activity on a worldwide basis. A listing of the more significant patents, sorted into groups relating to either formulations (12–21), manufacturing technology (22–29) or softgel design innovations (30–40), has been included in the reference section.

In 1990, there were 210 patents issued citing soft gelatin capsules as either specific claims or examples of

possible dosage forms. Over the past 12 months, approximately 760 patents were issued. Pharmaceutical application of soft gelatin capsule technology has increased over the past decade. This fourfold increase in the number of patents involving softgels may suggest a broader understanding of the benefits of this technology both in clinical performance as well as patient and consumer appeal.

Looking more closely at patents over the same period, there were 45 U.S. patents issued in 1990 where the soft gelatin capsule was a specific claim. The past 12 months yielded approximately 300 patents with softgels as a specific claim. This analysis is probably a better indication of patent activity specifically related to the softgel technology. This sixfold increase in the number of patents specifically involving softgel formulations may reflect greater and more widespread expertise with regard to softgel formulation processes. It may also be an indication of the greater proportion of "difficult" to formulate drugs currently coming out of basic research centers, that is, low aqueous solubility and/or poor or variable gastrointestinal absorption.

Examination of the patent activity of the top 20 pharmaceutical companies, or their predecessor companies, in the year 2000 vs. 1990 suggests an industry sector shift in the use of soft gelatin capsules. In 1990, the top 20 pharmaceutical firms obtained 85% of patents. This decreased to 57% over the past 12 months. Since overall pharmaceutical application of softgel technology has increased, a reasonable inference would be that the comparatively young and smaller biopharmaceutical industry sector is coming of age as compounds begin to move from basic research to development and commercialization.

Over the 1990 and 2000 periods, 95% of patents granted for pharmaceutical softgel products relate to drugs or fill formulations and not to specific claims or improvements regarding shell formulations or manufacturing processes. On the surface, this would appear to indicate a mature technology but since patents are public domain and process patents are difficult to enforce it is more likely that industry leaders are reluctant to pursue patents except in unusual circumstances. In this process-critical industry it is more reasonable to expect that companies prefer to maintain technological advances as internal know-how for competitive reasons.

CONCLUSION

Despite the specialized manufacturing process, softgels provide a versatile and efficient drug delivery system with

distinct advantages over conventional dosage forms, including improved bioavailability, shorter development times, superior patient preference, and enhanced dose uniformity. The inherent nature of the softgel offers a wide variety of usage and fill options. In any softgel product development effort, formulation of the fill and gelatin shell should be considered concurrently in order to optimize product quality and performance.

BLOOD SUBSTITUTES: THE FLUOROCARBON APPROACH

Jean G. Riess^a

University of California at San Diego, San Diego, California, U.S.A.

INTRODUCTION

Fluorocarbon emulsions provide a safe, efficient, and cost-effective passive means of delivering oxygen in vivo that does not depend on the collection of human or animal blood. Perfluorocarbons (PFCs, also designated as fluorocarbons or perfluorochemicals) are inert materials that have no ability to bind or react with oxygen, carbon monoxide, carbon dioxide, or nitric oxide. However, they can physically dissolve large amounts of these gases. PFCs are administered in the form of submicron size emulsions. The emulsifier utilized is egg yolk phospholipids (EYP), the same as that used for manufacturing fat emulsions for parenteral nutrition, with which PFC emulsions bear a definite similarity. Oxygen delivery to tissues by PFCs is facilitated by high extraction rates and ratios, the ability to increase oxygen content proportionally to oxygen partial pressure, and, in case of hemodilution, by increased cardiac output, resulting in large contributions to oxygen consumption relative to oxygen content. Phase 3 clinical trials have established the aptitude of such an emulsion to alleviate or reduce exposure to donor blood transfusions during surgery when used as part of the augmented acute normovolemic hemodilution procedure, which is one of the potential uses of blood substitutes. PFC emulsions thus have the potential to improve oxygen delivery, patient safety, and relieve blood shortages.

This entry will first survey the reasons for developing blood substitutes and outline the principles of oxygen delivery by PFC emulsions. It will then focus on the main challenges encountered in the development of such emulsions, namely the selection of an appropriate excretable PFC and the preparation of a stable, biocompatible emulsion. It will also allude to questions related to raw material procurement, product manufacture, and cost. Further sections will concern the pharmacokinetics, efficacy, and side effects of these oxygen carriers.

^aThe author is also a member of the Board of Directors of Alliance Pharmaceutical Corp. in San Diego; however, the opinions expressed here are solely his and not necessarily those of the Corporation.

Finally, the potential applications of these products will be outlined, including the status of their clinical trials, and some forward looking comments will be made.

OBJECTIVES—WHY BLOOD SUBSTITUTES?

Issues with Banked Blood

The blood supply of developed countries is now safer than it ever has been (1–3) although this is not the perception of the public. However, the risk associated with blood transfusion will never be completely eliminated. Further issues concern the immunodepressant effects of transfusions, and the lack of immediate efficacy of red blood cells (RBCs) stored for more than a few days. New legal questions have also arisen concerning, in particular, the extent of testing (4). Finally, blood shortages have become chronic in all areas of the world.

Safety

Acute anxiety about the safety of transfusion has developed following the AIDS tragedy. AIDS is only one of several infectious diseases transmitted by blood transfusion. Hepatitis is transmitted to recipients far more commonly than AIDS. Septic shock from bacterial contamination, although rare, does occur in certain areas (2). Malaria and Chagas disease are common in certain areas of the world (5). Other, as yet unknown, infectious agents are likely to emerge. The recent occurrence of a new variant of human Creutzfeldt–Jakob disease (nvCJD), which closely resembles bovine spongiform encephalopathy, raises serious public health concern (6, 7). Whether such encephalopathies are transmissible by transfusion is being debated (8, 9).

Blood transfusion is frequently associated with mild allergic reactions; more serious hemolytic transfusion reactions, transfusion-related acute respiratory distress syndrome, and even fatal acute hemolytic transfusion reactions are rare but do exist (2, 3). Finally, administrative errors remain one of the main causes of transfusion-related morbidity and mortality.

Additionally, there is increasingly strong evidence that allogeneic blood transfusion reduces the immune

responsiveness (or immunocompetence) of the organism, thus predisposing a transfusion recipient to infectious complications and septicemia (10–12). Fewer infections were observed in patients receiving autologous rather than allogeneic blood (13, 14). Mortality in patients with sepsis was associated with the age of the RBCs transfused (15). Intraoperative blood transfusion was also associated with an enhanced inflammatory response, increased concentrations of inflammatory mediators, and increased post-operative morbidity in patients undergoing cardiac surgery (16). Blood transfusion has been identified as a risk factor for postinjury multiple organ failure in trauma patients (17).

Blood transfusions also appear to increase the risks of recurrence and spread of certain cancers (10, 18, 19), and to reduce long-term survival following surgery (20). This risk may again be lower when autologous rather than allogeneic blood is used (21).

Whatever the level of risk associated with a unit of blood, this risk is cumulative with the number of units transfused; conversely, each unit spared to a patient reduces the risk of transfusion-related side effects.

Efficacy

Refrigeration and storage of RBCs results in so-called storage lesions, which include changes in the affinity of hemoglobin for O₂, decrease in pH, hemolysis, changes in RBC deformability, formation of microaggregates, release of vasoactive substances, and denaturation of proteins (22). After 2 weeks, little 2,3-diphosphoglycerate (2, 3-DPG), the allosteric factor that facilitates O₂ release to tissues, is left. As a result, transfusion of stored blood is not immediately effective in delivering O₂. It takes actually about 24 h for banked RBCs to restore their 2, 3-DPG level to about half of normal. In contrast to fresh RBCs, 28-day-old RBCs failed to improve tissue oxygenation in severely hemodiluted rats (23). A new important awareness is thus emerging: Banked blood (including predonated autologous blood) is not equivalent to *fresh* blood.

Availability

In developed countries blood collection is declining as a result of the aging of the populations, the development of aggressive new therapies, and the increase in the number of patients undergoing elective surgery (3). Blood shortages are increasingly frequent, leading to increasingly frequent postponement of elective surgeries. Further substantial increases in demand and decrease in donation are anticipated (22, 24, 25). Any additional steps to improve safety will invariably result in deferral of donors, hence directly impacting blood availability. If safety increases at the expense of availability, people may eventually die from lack of blood.

In the emerging countries, blood is chronically short due, among other things, to the limited number of suitable and/or willing donors. Viral or parasitic infection with blood-borne diseases can lead to the rejection of a large proportion of the units collected. In addition, the infrastructure and training required to collect, store, and deliver the available supply are sometimes lacking.

What is Expected from Blood Substitutes?

The products under development are not substitutes for blood; they only fulfill the O₂/CO₂ exchange function of blood and only for a short duration. They assume none of the regulation, defense, and coagulation functions of blood. Effective O₂ carriers would nevertheless be precious for the duration of a surgical procedure. In addition, they could ensure tissue oxygenation in situations where blood is no longer able to do so.

To be of value, O₂ carriers need to be able to load O₂ rapidly during passage of the blood through the lungs, reach the tissues at risk of ischemia, and deliver the O₂ load rapidly and maximally to these tissues. They must be free of bacteria and viruses, and should not promote the development of pathogens. They must be devoid of antigenic effects, and their side effects must be clinically minimal. They should preferably be devoid of physiological activity other than O₂ delivery. It is also essential that they preserve the increase in cardiac output that normally follows hemodilution. Ideally, they should have prolonged circulation lives. Use of O₂ carriers should eliminate clerical errors and the risk of transfusion incompatibilities. It is essential that the products be ready for use, easy to handle, and immediately effective. They must also be manufacturable on a large scale from safe raw materials, preferably be heat sterilized and stable enough to allow long-term storage under standard conditions. Finally, they need to be cost effective.

All the present O₂ carriers, whether fluorocarbon- or hemoglobin-based, have short circulation half-lives, a reality that needs to be taken into account in their use. This limitation, however, does not restrict use during surgery (which consumes about 60% of all blood collected), potentially reducing or avoiding exposure to allogeneic blood. An artificial O₂ carrier could also serve as a bridge to transfusion in case of emergency or during the time required for administered stored RBCs to restore their O₂-delivery capacity. A blood substitute that does not rely on human blood collection could play a considerable role in helping to relieve blood supply shortages. When combined with appropriate surgical procedures, blood substitutes could make the patient become his or her own blood

donor. For the developing countries, the availability of a blood substitute may be the best hope to meet future health care needs.

One difficulty concerning the evaluation of injectable O₂ carriers from a regulatory standpoint comes from the absence of a standard with which to compare them. Blood or RBCs have never been subjected to a controlled clinical trial for demonstrating their efficacy and have never been formally approved by a regulatory agency (26, 27). The same holds for the autologous transfusion alternatives, including preoperative donation and normovolemic hemodilution. Substantial efforts have been devoted to defining proper clinical endpoints that allow determining whether or not administration of an O₂ carrier translates into clinical benefit. Avoidance of transfusion of allogeneic blood during surgery appears now to be an accepted endpoint for such products.

PRINCIPLES OF OXYGEN DELIVERY BY PERFLUOROchemicals (26)

Stable and Passive Gas Solvents

PFCs are essentially made of carbon and fluorine instead of carbon and hydrogen as are most organic compounds. Transport of O₂ by PFCs relies on dissolution of the gas in a biocompatible liquid solvent, rather than on chemical binding to the carrier molecule as in the case of hemoglobin. The reason for using PFCs for in vivo O₂ delivery is their unique combination of high gas-dissolving capacity (the highest known among liquids), and exceptional chemical and biological inertness (they are among the most stable organic materials ever invented). The first of these properties is a direct consequence of the weakness of the cohesive forces (van der Waals interactions) between molecules in liquid PFCs, which facilitates the insertion of gas molecules within the liquid. The PFCs' inertness, on the other hand, reflects the strength of the intramolecular covalent bonds, and the high ionization potential and low polarizability of the fluorine atoms. The C—F bond is the strongest single bond encountered in organic chemistry. The bonds between perfluoroalkyl (*F*-alkyl; the prefix *F*-indicates that all hydrogen atoms are replaced by fluorine atoms in the structure) chains and oxygen, nitrogen, chlorine, or bromine are also usually strengthened. The high electron density of the fluorine atoms results in a compact, repellent electron shield that ensures effective protection of the molecule's backbone. PFCs are not subject to oxidation and do not undergo any reaction under the conditions of processing, storage,

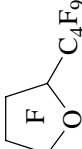

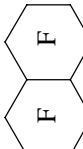

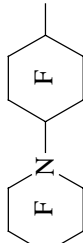

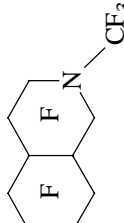

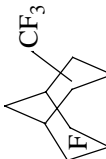

and use relevant to therapeutic O₂ delivery. Neat PFCs typically resist heating to 300°C, and PFC emulsions can be heat sterilized at 121°C. No enzymatic system is known to digest PFCs, and no microorganism is known to feed on them. PFCs are extremely hydrophobic, as well as lipophobic, which also contributes to their biocompatibility and largely determines their excretion rates. Table 1 lists the PFCs that have been most thoroughly investigated for the purpose of developing an injectable O₂ carrier.

The amount of gas dissolved in a PFC obeys Henry's law, i.e., is directly proportional to the partial pressure of the gas (Fig. 1). Since no chemical bonding is involved, there is no saturation. Uptake and release of O₂ by PFCs is essentially insensitive to temperature and environment. Oxygen content can be adjusted by simply controlling pO₂. The O₂ solubilities of the PFCs pertinent to intravascular use range from 40 to 50 vol% under one atmosphere (Table 1); i.e., they are larger than in water by a factor of 20 or more (28). Linear PFCs have an advantage over cyclic and polycyclic ones (29). The CO₂ solubilities of PFCs range from 140 to 240 vol%.

Pure Synthetic Carriers

Two major strategies are available for manufacturing PFCs, which consist either of substituting fluorine atoms for hydrogen atoms in the direct hydrocarbon analog of the desired PFC, or of combining smaller, already fluorinated, reactive building blocks to form the target PFC (30). Electrochemical fluorination in hydrogen fluoride, fluorination by high-valency metal fluorides (usually cobalt trifluoride) and direct fluorination by elemental fluorine, belong to the first category, while telomerization of tetrafluoroethylene (TFE) belongs to the second. Because of the higher strength of the C—F bond as compared to the C—H bond, substituting fluorine for hydrogen on carbon involves the release of large amounts of energy and results usually in complex mixtures. Yet several PFCs prepared by substitution methods have been used in O₂ carrier development (Tables 1 and 2). Telomerization, on the other hand, readily provides highly pure linear PFCs. Telomerization involves the reaction of a telogen, such as C₂F₅I, with an olefin, such as TFE, to form a series of longer PFC products, the telomers, in high yields. Examples of PFCs derived from telomerization of TFE include *F*-octyl bromide **1** (PFOB, also known as perflubron) and *F*-decyl bromide **2** (PFDB), the O₂-carrying components of *Oxygent*TM AF0144, an emulsion currently developed by Alliance Pharmaceutical Corp. (San Diego, California)

Table 1 Perfluorocarbons most thoroughly investigated for injectable oxygen carriers development^a

Structural formula	Code name (MW)	Preparation procedure (Purity)	Boiling point (°C), Vapor pressure (torr, 37°)	Solubility O ₂ , CO ₂ (vol%, 37°)	RES half-life (days)

and 1,2-bis(*F*-butyl)ethene **3** (code-named F-44E), which is utilized by Neuron Therapeutics, Inc. (Malvern, Pennsylvania) for the development of an emulsion for the treatment of stroke (31).

Injectable Emulsions

Because they are virtually insoluble in water, PFCs are formulated as emulsions for parenteral administration. Obtaining stable, biocompatible, small-sized, narrowly distributed emulsions of an excretable PFC was crucial. The extreme hydrophobicity of PFCs can, however, render the obtaining of a stable emulsion difficult. Further critical aspects of PFC emulsion development involve emulsion formulation, physical and biological characteristics, scale-up, sterilization, and packaging, as well as its user-friendliness and strategy of use.

The submicron-size PFC droplets are coated with a thin layer of a surfactant that serves as an emulsifier and an emulsion stabilizer. A range of emulsion concentrations—from 20–100% w/v (i.e., about 11–52 vol%)—has been investigated (31–34). The present PFC emulsions use EYP as the emulsifier. These emulsions are, therefore, very similar to the Intralipid®-type parenteral lipid emulsions. Emulsion osmolality is independent of PFC concentration and is adjusted with salts or other tonicity agents. Particles of less than 0.2 μm evade phagocytosis more easily than larger ones, resulting in longer intravascular persistence and lesser side effects. Contrary to Hb solutions, PFC droplets do not normally filter out of the circulation.

Modest Oxygen-Transport Capacity that Translates into High Oxygen-Delivery Efficacy

Introducing a PFC emulsion into the circulation is akin to increasing the O_2 solubility of the plasma compartment of blood. The principles that underlie O_2 transport by the PFC and plasma are essentially the same. In both cases dissolution is proportional to pO_2 ; simply, the solubility of O_2 in PFCs is typically 20 times larger than for the plasma (28). The amount of O_2 dissolved in a given PFC emulsion is the product of the PFC's O_2 solubility coefficient, emulsion concentration, and O_2 partial pressure (Fig. 1). It is, for example, ~ 3 vol% at 37°C in a 60% w/v emulsion of PFOB in room air, and ~ 16 vol% in pure O_2 . In the blood of a patient breathing pure O_2 , the arterial O_2 tension is increased to about 500 torr and the emulsion will carry about 10.5 vol% of O_2 .

Oxygen release by PFCs to tissues is not dependent on a change in conformation of the PFC molecule or any cooperative effect, and does not require the assistance of an allosteric effector. It is greatly facilitated as compared to hemoglobin because the van der Waals interactions between O_2 molecules and PFCs are an order of magnitude weaker than the covalent $\text{O}_2\text{—Fe(II)}$ coordination bond, resulting in much higher extraction rates and ratios. The latter typically reach 90% with PFC emulsions as compared to about 25% for hemoglobin in normal conditions (35,36). This amounts to about 9.5 vol% O_2 for the above-mentioned *F*-octyl bromide emulsion. Oxygen release from PFCs is effective at any physiologically relevant partial pressure, rendering a cooperativity-like effect unnecessary. Likewise, O_2 release by PFCs is not dependent on pH and is not adversely affected by temperature. Since PFCs do not undergo oxidation or other modification over time, their O_2 uptake and release characteristics are not affected by storage. When hemoglobin and a PFC are present in the circulation simultaneously, the PFC will release its O_2 load first, thus conserving the O_2 bound to the hemoglobin.

Hemoglobin is exquisitely well adapted to supporting life in earth's atmosphere, but the conditions available in the operating room or critical care unit are different, and adjustable. A valuable consequence of O_2 dissolution in PFCs following Henry's law is that the transport capacity of a PFC emulsion can be increased by a factor of five by just increasing the fraction of O_2 in the air inspired by the patient (FiO_2).

Hemoglobin solutions and PFC emulsions thus cannot be compared on the sole basis of their static O_2 -binding or O_2 -dissolving capacities on a gram-per-gram basis in air. Such an approach would overlook the approximately fourfold higher tissue O_2 extraction ratio that is seen with

Table 2 Perfluorocarbon emulsions having reached some degree of commercial development

Trade name	Company	Perfluorocarbon ^a	Concentration v/v (w/v)	Surfactants	Remarks	Status (Sept. 2000)

PFCs under normal conditions, and ignores the possibility of increasing O₂ dissolution in PFCs by a factor of almost five simply by giving the patient pure O₂ instead of air to breathe; i.e., ignores the actual conditions in which PFC products are to be utilized.

Eventually it is the amount of O₂ that is delivered to the tissues and the carrier's contribution to tissue O₂ consumption, $\dot{V}O_2$, that determines its effectiveness. Oxygen delivery, $\dot{D}O_2$ (the amount of O₂ offered to the tissues within a defined period of time), is the product of arterial blood O₂ content, CaO₂, and the cardiac output, CO (Eq. 1):

$$\dot{D}O_2 = (CaO_2) \times CO \quad (1)$$

When normovolemic hemodilution is performed, there is normally a substantial increase in cardiac output as a result of increased fluidity of the diluted blood (37–39). This increase in cardiac output is preserved when PFC emulsions are administered, which further enhances their O₂-delivery capacity (39, 40), while cell-free Hb products, because of vasoconstrictive effects, classically display an unchanged or reduced cardiac output that can negate the benefit of increased fluidity (41, 42).

The large pO₂ gradients that set in place at the high FiO₂ at which PFCs are utilized provide a strong driving force for O₂ diffusion from the PFC droplets to the tissues. The emulsion droplets being typically in the 0.1–0.2 μm size range, i.e., 30–70 times smaller than RBCs, circulate more easily in the capillary beds than RBCs. They will be present in large numbers in the plasma gaps that exist between red cells in the microcirculation, thereby increasing O₂ content. These plasma gaps are particularly large when the patient suffers from acute anemia or when hemodilution is practiced. It is likely that PFC particles not only transport O₂, but also facilitate its diffusion from RBCs to the tissues by providing numerous “stepping stones” or dynamic chains of particles for O₂ to travel on (36, 43). The effectiveness of PFC emulsions is expected to be greatest in the capillary beds, at low RBC concentrations, and when FiO₂ is high. Altogether, the contribution of PFCs to O₂ delivery and to tissue pO₂ can thus be highly significant, even though the amount of PFC-dissolved O₂ in the circulation is smaller than the amount of Hb-dissolved O₂.

The O₂ tension of the mixed venous blood, P $\bar{v}O_2$, i.e., the residual O₂ tension after the tissues have extracted the O₂ they needed, is often used as a global indicator of tissue oxygenation. A substantial increase in P $\bar{v}O_2$ was consistently observed upon administration of PFC emulsions and was paralleled by an increase in tissue pO₂ (36, 39, 44, 45). A physiological model was

developed that allows calculation of the contribution of a given dose of PFC to a given patient and was validated using clinical data (46). The contribution of the PFC to O₂ consumption could thus be described in terms of an “hemoglobin equivalent” value (47).

Early Emulsions—Fluosol®

The first physiologically adjusted emulsion of a PFC (*F*-butyltetrahydrofuran, FX-80, **4**) was used in 1967 (48) for oxygenating isolated rat brain. Shortly after, virtually all the RBCs of O₂-breathing rats were successfully replaced with a poloxamer-stabilized emulsion of *F*-tributylamine (FTBA, **5**) (49). FTBA was, however, retained in the animal's organs for an exceedingly long time. Fortunately, it was discovered that *F*-decalin (FDC, **6**) was excreted within a few weeks of its administration (organ half-life of about 7 days) (50, 51). However, it was realized that PFCs that gave stable emulsions were retained in the organism for an unacceptably long period of time, while PFCs that were excreted rapidly did not produce emulsions stable enough for practical use (29).

The first commercially developed emulsion, Fluosol-DA (Green Cross Corp. Osaka, Japan), was stabilized using a mixture of **6** and *F*-tripropylamine (FTPA, **7**, 30% of total PFC) (Table 2) (52, 53). However, the product's stability was still poor: Fluosol had to be frozen for shipment and storage, and reconstituted prior to use. Fluosol utilized a surfactant system that included poloxamer-188 (Pluronic® F-68) with smaller amounts of EYP and potassium oleate. The poloxamer provided steric stabilization, and potassium oleate introduced negative charges on the droplets, likely to oppose flocculation.

Another 20% w/v emulsion, trade-name Perftoran, based on an FDC and *F*-[1-(4-methylcyclohexyl)piperidine] (FMCP, **8**) mixture emulsified with a poloxamer was developed in Russia (Russian Academy of Sciences/Perftoran Company, Pushchino, Russia) (43, 54). Perftoran is filter-sterilized and stable for about 1 month at 4–8°C but requires freezing for longer storage. The Russian health authorities licensed it in 1997 for a wide range of indications. A highly stable 20% w/v *F*-tributylamine/Pluronic F-68 emulsion, Fluosol-43 (later renamed Oxypherol) (52), was commercially available for many years for experimental use.

SECOND GENERATION EMULSIONS (26)

Fluosol's shortcomings included prolonged organ retention of *F*-tripropylamine (reticuloendothelial system

(RES) half-life 65 days), complement activation, and hemodynamic effects due to Pluronic, excessive dilution, limited intravascular persistence, insufficient stability, and lack of user-friendliness. The product came as three separate preparations: the frozen stem emulsion and two annex salt solutions. The stem emulsion had to be carefully thawed, then admixed sequentially to the annex solutions, and the reconstituted product had to be used within 8 h. This cumbersome procedure, the short window for use, the further need for administering a small-test dose to patients prior to infusion in order to identify those patients who were sensitive to *Pluronic*, contributed to compromising the product's commercial success.

Assessment of Fluosol established that the emulsion did carry and deliver the expected amount of O₂ to tissues. It also established that large doses of PFCs could be administered without significant side effects and provided valuable information on the pharmacology of PFCs. An essential point learned from the development of Fluosol was that PFC emulsions needed to be ready for use, hence significantly more stable. At least 1 year of shelf stability under standard refrigeration storage conditions was indispensable. Particles needed to be small (0.1–0.2 μm) and remain as such during heat sterilization and throughout the product's shelf life, as small particle sizes translate into longer intravascular persistence and reduced side effects (55–57). It was also deemed necessary that the emulsion be relatively concentrated, yet fluid. The choice of a 60% w/v PFC concentration was determined by convenience of use in surgical applications, and marketing and manufacturing considerations.

SELECTING THE FLUOROCARBON—PERFLUOROOCTYL BROMIDE

Selection of an appropriate PFC and the production of a stable emulsion are key to the development of a safe and effective PFC-based O₂ carrier. The principal selection criteria for the PFC are rapid excretion and the aptitude at giving stable emulsions. Candidate PFCs also need to have high O₂ solubility and be well tolerated. Additionally, the selection process must take into account the PFC's manufacturability and cost.

Excretion was determined to be primarily an exponential function of the PFC's molecular weight (MW, Fig. 2). Structural features such as cyclization, branching, or the presence of heteroatoms have little influence other than changing the PFC's MW. The dependence of excretion rate on MW is consistent with the realization that excretion requires a certain degree of volatility and solubility of the

Fig. 2 Semilogarithmic plot of organ retention half-times for PFCs, as a function of molecular weight. Open symbols indicate PFCs with lipophilic character; F-nn'E: n and n' represent the number of carbon atoms in the homologous series C_nF_{2n+1}-CH=CHC_nF_{2n'+1}, i = iso; for the other symbols see Table 1.

PFC in lipids. However, as MW diminishes, vapor pressure tends to increase, which can eventually cause pulmonary complications (52, 58), thus setting an upper limit (around 20 torr) to the PFC's acceptable vapor pressure. The range of MWs adequate for intravenous administration was eventually established to be narrow (approximately 460–520) (29).

A candidate PFC was eventually identified that had a shorter organ-retention time than would have been predicted on the sole basis of its MW and was amenable to producing stable emulsions. This PFC was 1-*n*-*F*-octyl bromide (PFOB, 1). PFOB had initially been investigated because the radiopacity provided by its bromine atom allowed its use as a contrast agent (59).

PFOB's exceptionally fast excretion rate (~3 days in humans for a 2.7 g/kg dose) was attributed to the slightly lipophilic character induced by its well-exposed terminal bromine atom. This lipophilic touch facilitates uptake of the PFC by circulating lipids and transit through the organism (60, 62). In addition, this PFC can be manufactured in better than 99.9% purity. A 100-ton/year production capacity is already in place, which can easily be scaled higher. PFOB also ranks amongst the PFCs that have the highest O₂ and CO₂ solubilities (Table 1). Its emulsions show improved stability when phospholipids are the emulsifier. Its very low surface tension and positive spreading coefficient are advantageous in liquid ventilation, an application of PFOB that is currently in advanced clinical evaluation. Table 3 collects some of the physicochemical features of PFOB and FDC, and

Table 3 Physical properties of *F*-octyl bromide (PFOB, **1**) and *F*-decalin (FDC, **6**)

Property (units)	Symbol	PFOB	FDC (<i>cis</i> + <i>trans</i>)
Molecular formula		C ₈ F ₁₇ Br	C ₁₀ F ₁₈
Molecular weight (g/mol)	M_w	499	462
Molar volume (cm ³ /mol)	V_m	261	237
Molecular volume (Å ³)	V	432	393
Density (g/cm ³ , 25°C)	ρ	1.92	1.94
Melting point (°C)	m.p.	5	−10
Boiling point (°C)	b.p.	143	142
Vapor pressure (torr, 37°C)	v.p.	10.5	14
Heat of vaporization (kJ/mol)	ΔH_v	4.83	45.8
Refractive index (25°C)	n_D	1.30	1.313
Kinematic viscosity (centistokes, 25°C)	ν	1.0	2.9
Surface tension (mN/m)	σ	18.0	15
Interfacial tension vs. saline (mN/m)	σ^i	51.3	~60
Spreading coefficient (mN/m)	S (o/w)	+2.7	−1.5
O ₂ solubility (vol%, 25°C)	[O ₂]	50	40
CO ₂ solubility (vol%, 25°C)	[CO ₂]	~210	~140
Critical solution temperature (<i>n</i> -hexane, °C)	CST (hexane)	−20	+22
Solubility in water (mol/L)		5×10 ^{−9}	10×10 ^{−9}
Solubility in olive oil (mmol/L)		37	4.6

illustrates the differences that can exist among PFCs, including O₂ solubility, lipophilicity, viscosity, surface properties, and solubility in water (31). Another somewhat lipophilic fluorocarbon, α,ω -dichloro-*F*-octane (PFDCO, **9**), has been selected for development of another concentrated EYP-based PFC emulsion, Oxy-fluor[®] (HemaGen/PFC, St. Louis, Missouri) (63).

Selecting the Emulsifier—EYP

Proper selection of a biocompatible emulsifier or emulsifier system was also essential for successful PFC emulsion development. One of the emulsifier's roles is to reduce the large interfacial tension (σ^i) that opposes the dispersion of the very hydrophobic PFC ($\sigma^S \leq 20$ mN/m) into water ($\sigma^S = 72$ mN/m, 20°C). Another is to stabilize the emulsion once it is formed. The only two surfactants used in PFC emulsion development so far are poloxamers and phospholipids.

Poloxamers are neutral block copolymers such as **12**, consisting of two terminal hydrophilic polyoxyethylene blocks flanking a central hydrophobic polyoxypropylene block. Poloxamer 188 (e.g., Pluronic F-68) was used in the first generation PFC emulsions, but was far from adequate: Its surface activity is relatively poor, translating into low emulsions stability; the purity of the commercial products is usually rather low; its cloud point (~ 110 – 115°C)

prevents sterilization at the standard temperature of 121°C; its tendency to form gels limits the PFC concentration in the emulsions; and, finally, Pluronic F-68 has been found to be responsible for the unpredictable transient complement activation-mediated anaphylactic reaction observed in some patients in response to the injection of Fluosol (64–66).

EYP have been chosen as the emulsifier in all second generation PFC emulsions. EYP, whose major constituents are the amphiphilic amphoteric phosphatidylcholines **13**, provide significantly better emulsion stability than poloxamers. The stabilization effect is particularly remarkable with PFOB (31, 67, 68). Emulsions of PFCs prepared with EYP do not cause complement activation (56, 65). Phospholipids have a long history of use in pharmaceuticals; their pharmacology is well documented and there exist reliable commercial sources

of pharmaceutical grade EYP. The hydrolysis of EYP in PFC emulsions is minimal when pH is close to neutral; its oxidation can be minimized by adding small amounts of a metal chelator and an antioxidant, and through manufacture and packaging under nitrogen.

Stabilizing the Emulsion—A Lipophilic “Heavier” Perfluorocarbon

Stability is an essential condition for PFC emulsions to be of practical use. The principal mechanism for irreversible droplet growth in submicronic PFC emulsions during storage is molecular diffusion (also known as Ostwald ripening or isothermal distillation) (29,31,69,70). Coalescence may contribute to instability when mechanical stress is applied and at higher temperatures, as during heat sterilization. Sedimentation and flocculation are fully reversible and pose no problem. Molecular diffusion involves the transfer of individual PFC molecules from the smaller droplets, where the chemical potential is higher due to the higher curvatures of the particles (Kelvin effect), through the continuous aqueous phase to join larger ones, resulting in irreversible increase of droplet size over time. The Lifshitz–Slezov–Wagner theory predicts a linear increase in number average particle radius \bar{a} versus time (Eq. 2) (31,70,71), which was consistently observed experimentally with PFC emulsions (Fig. 2):

$$\frac{d}{dt}(\bar{a}^3) = \omega = \frac{8\sigma^i DC(\infty)V_m}{9RT} \gamma(\phi) \quad (2)$$

Of the parameters of Eq. 2, only $C(\infty)$, the solubility of the PFC in the aqueous phase, varies significantly among PFCs, resulting in a dramatic effect on particle size growth over time (Fig. 3).

Molecular diffusion in emulsions can be effectively slowed down by including in the dispersed phase a small amount of a component with lesser water solubility (71), in the case of a PFC emulsion, a secondary, higher MW (“heavier”) PFC (31,69,70). This is the role of **7** in Fluosol and of **8** in Perftoran, however, at the cost of longer organ half-lives of ~65 and ~90 days, respectively.

In *Oxygent* AF0144, the inevitable increase in organ retention with increasing MW was mitigated by choosing a *lipophilic* homolog of PFOB, PFDB (RES half-life of about 25 days), as the “heavy” stabilizing additive (31,62).

Fluorinated surfactants (or fluorosurfactants, i.e., surfactants with hydrophobic tails comprising a fluorocarbon moiety) provide an alternative means of achieving

Fig. 3 Particle size increase over time for emulsions made of diverse PFCs and surfactants (F-68: Pluronic F-68; for the other symbols see Table 1). (Adapted from Ref. 32.)

extremely stable PFC emulsions, as they can provide very low PFC/water interfacial tensions (σ^i , another factor in Eq. 2) (72). As yet, this option has not been developed, in part because of the added cost involved in the evaluation for approval of a novel active excipient. A further means of effectively increasing the stability of EYP-based PFC emulsion consists of supplementing standard phospholipids with mixed fluorocarbon–hydrocarbon diblock compounds, such as **14** or **15** (73). Such diblocks, which have fluorophilic–lipophilic amphiphilic properties, are expected to improve the adhesion of the phospholipid film onto the PFC droplet.

Raw Material Procurement and Emulsion Manufacture

Reliable access to raw material, ease of manufacture, and cost-effectiveness will play a critical role in determining the degree of acceptance, breadth of application, and commercial success of an O₂ carrier. To have a significant impact on medical practice, O₂ carriers must be able to replace a fair proportion of the blood and packed RBCs that are presently being transfused. A mere 10% of this amount represents over one million RBC units in the United States alone and several million units worldwide. Only O₂ carriers that can be produced in that order of magnitude at a cost that remains in the vicinity of that of blood, can potentially mitigate the current and projected blood shortages.

PFCs, being synthetic, have obvious advantages from the standpoints of raw material procurement, purity, safety, and cost-effectiveness. Highly pure PFCs can be manufactured, in any desired amount, within tight specifications, using well-established procedures. PFOB, for example, is directly derived from the production line that leads to polytetrafluoroethylene (e.g., Teflon®) and to diverse large-tonnage industrial surfactants.

Technology for large-scale production of injectable emulsions in compliance with good manufacturing practices is well established in the pharmaceutical industry. Manufacture of a sterile PFC emulsion for parenteral use, although it relies on existing technologies, required the development of specific know-how. Egg phospholipids have a long history of use in pharmaceuticals, including preparation injectable lipid emulsions and, more recently, liposomes. The formulation process for PFC emulsions being additive, its yield is essentially quantitative with respect to the raw materials utilized. The present products are terminally heat-sterilized in standard conditions. The investment in a given size production unit may probably be as much as an order of magnitude lower for PFC emulsions than for any hemoglobin product. Small-size PFC particles and narrow-size distributions have been achieved reproducibly.

For EYP-based PFC emulsions, the first step of the process involves dispersing of the water-insoluble phospholipid in a saline solution. The PFC is then added to this saline phase, where it is broken down into fairly large droplets (av. $\sim 5 \mu\text{m}$) with a high shear rotor-stator type homogenizer. This premix undergoes final emulsification, using a high-pressure homogenizer that provides a high-energy density (31). Minimal exposure to oxygen (through nitrogen sparging and blanketing), pyrogen-free water-for-injection and a particulate-free environment are used throughout processing. The Gaulin-type high-pressure homogenizer is the equipment of choice for

industrial production of pharmaceutical emulsions as it is easy to control, gives narrow, consistent particle size distributions and can be operated on very large scales.

The Current *Oxygent* AF0144 Emulsion

A concentrated (60% w/v) PFOB/PFDB emulsion (*Oxygent* AF0144) is currently being produced in a commercial-scale facility (31). The emulsion is steam-sterilized in a rotary autoclave at or above 121°C, using a procedure that achieves uniform heat penetration, maintains emulsion integrity, and provides the required probability of less than one nonsterile unit in 10⁶. As compared to Fluosol, *Oxygent* is characterized by use of PFCs having some lipophilic character, use of phospholipids as the emulsifier instead of poloxamer, a several-fold increase in PFC concentration, simplification of the overall formulation, considerable increase in stability, and consequently, far superior convenience of use.

Oxygent AF0144 is a ready-for-use, pH-balanced, isotonic fluid emulsion of *F*-alkyl bromides. It comprises 60 wt% PFC (about 32 vol%) consisting primarily of PFOB (AtoFina, Pierre Bénite, France), a small percentage of PFDB as the stabilizing additive and EYP as the emulsifier. Osmolarity is adjusted with NaCl, and pH with a phosphate buffer. Minute amounts of α -D-tocopherol and EDTA are included to protect the phospholipids against oxidation. Average droplet size, after heat sterilization, is about 0.16 μm and viscosity around 5 cP (extrapolated at zero shear rate). The product has a shelf life of at least 18 months at 5–10°C (31). Other post-Fluosol formulations with EYP as the emulsifier are listed in Table 2.

PHARMACOKINETICS

The PFC droplets in the circulation are opsonized and progressively cleared from the blood stream by circulating monocytes and fixed macrophages of the RES, the larger droplets being removed first. This mechanism is responsible for the limited intravascular persistence of the emulsion. The PFC is temporarily stored in the primary organs of the RES, the liver, spleen, and bone marrow. Subsequently, the PFC molecules slowly diffuse across cell membranes (the rate determining step) from the RES organs back into the blood, where they are taken up by circulating lipid carriers (lipoproteins and chylomicrons) (31, 56, 60, 74). The rate of these steps depends critically on the PFC's MW and lipophilicity. The PFC is eventually excreted unchanged from the blood through the alveoli in the expired air. Some of the PFC also distributes into

adipose tissue and other lipid-containing tissues, before being excreted by the same pathway as above. There are no reports of PFC metabolism or enzymatic degradation.

The emulsion's circulatory half-life, $t_{1/2}$, is particle size-, species-, and dose-dependent. It increases significantly when the size of the droplets decreases (52, 57). Dose-dependence in humans is illustrated by $t_{1/2}$ values of 7.5 and 22 h for doses of 4 and 6 g of PFC/kg, respectively, for Fluosol (52), and 6.1 and 9.4 h for doses of 1.2 and 1.8 g/kg, respectively, for *Oxygent* (75). Particles of less than 0.2 μm are preferable, as they facilitate O_2 diffusion and are less rapidly phagocytized than larger particles, resulting in longer intravascular persistence and fewer side effects. The effects of PFCs on RES organ morphology and function have been thoroughly investigated, found fully reversible, and considered nondetrimental (56, 76, 77).

Four-compartment pharmacokinetic models (PFC emulsion in blood, PFC in RES tissues, PFC in non-RES tissues, PFC dissolved in blood lipoproteins) indicated that the rate-determining step in PFC excretion was the dissolution of the PFC into lipid carriers, confirming the critical importance of the lipid solubility of the PFC in the excretion process (31).

EFFICACY

The efficacy of PFC emulsions at delivering O_2 in vivo has been established in numerous experimental animal models and in clinical trials with first and second generation products. Oxygen-breathing animals, exchange-perfused with PFC emulsions to an hematocrit of 1%, have been shown to survive the exchange (49, 67). Mixed venous O_2 tension, $\text{P}\bar{\text{v}}\text{O}_2$, increased significantly in spite of decreased total arterial O_2 content. When RBCs were present, hemoglobin remained close to fully saturated with O_2 .

Clinical trials conducted with Fluosol have established that the product could contribute meaningfully to O_2 consumption in anemic patients and had an immediate beneficial impact on the condition of these patients (78–81). For example, administration of a 4 g/kg body weight dose of PFC to severely anemic O_2 -breathing surgical patients, while only increasing arterial O_2 content by a modest 0.8 vol%, provided 7% of the O_2 delivered and a significant 24% of the patient's O_2 consumption (78). $\text{P}\bar{\text{v}}\text{O}_2$ was seen to increase by approximately 60%, and the mixed venous Hb saturation ($\text{S}\bar{\text{v}}\text{O}_2$) reached 90%. The amount of O_2 provided by Fluosol was deemed clinically important. Another study with highly anemic surgical patients confirmed that Fluosol unloaded O_2 very effectively and contributed at least as much to O_2

consumption ($28 \pm 7\%$) as the patients' own RBCs (79). However, the benefit being short-lived, the outcome for patients who refused blood transfusion on religious grounds could not be improved, indicating that treatment of sustained anemia was not a valid indication for such a product. As a logical result, the Food and Drug Administration did not approve Fluosol in the United States when submitted for this indication in the early 1980s. Subsequent approval of Fluosol in 1989 for use during an angiography procedure in high-risk patients implies that both efficacy (reduced ischemia of the myocardium (82, 83)) and safety had been demonstrated for this application. Fluosol did not gain acceptance, not for lack of efficacy in delivering O_2 or because of side effects, but because of poor stability, inappropriate indication and strategy of use, and because of the development of autoperfusion catheters for the percutaneous transluminal coronary angioplasty procedure.

The efficacy of *Oxygent* AF0144 in terms of improving systemic oxygenation status has been demonstrated in various animal models (39, 84) as well as in surgical patients (85). The capacity of PFCs to contribute significantly to O_2 delivery was in agreement with computer simulation. For example, a 2.7 g PFC/kg dose administered to O_2 -breathing dogs, while contributing only 8–10% to total blood O_2 content, accounted for 25–30% of total O_2 consumption, $\dot{\text{V}}\text{O}_2$ (84) allowing O_2 consumption to be maintained while Hb levels were decreased to values

Fig. 4 Efficacy of *Oxygent* in a canine model mimicking surgical blood loss after acute normovolemic hemodilution. Both the treatment group and the control group were hemodiluted to a hemoglobin level of 8 g/dl, breathed oxygen and lost blood, hence hemoglobin (x axis). Change in $\text{P}\bar{\text{v}}\text{O}_2$ relative to O_2 -breathing baseline during volume-compensated blood loss (y axis) is significantly different between the two groups. (From Ref. 45.)

as low as 2.0 g/dl (Fig. 4). The PFC-treated dogs could lose almost 70 ml of blood per kg (about two-thirds of their blood), compared to 10 ml/kg in controls, before $P\bar{v}O_2$ fell below the initial 100% O_2 -breathing baseline. Tissue pO_2 of skeletal muscle, gut, and brain was seen to increase substantially. Another study of this type concluded, on the basis of both indirect global indicators ($P\bar{v}O_2$, $\dot{V}O_2$) and direct measurements of tissue pO_2 on the surface of liver and skeletal muscle, that the emulsion was as effective as fresh autologous RBC transfusion in maintaining tissue oxygenation during volume-compensated blood loss designed to simulate surgical bleeding (39). Hemodilution of the dogs could be extended to a 3 g/dl Hb level without impairment of tissue oxygenation. Likewise, dogs that had been hemorrhaged until their $P\bar{v}O_2$ was equal to or less than 25 torr, when resuscitated with Oxyfluor, restored their $P\bar{v}O_2$ and all survived, while only 62% of the Ringer's solution-treated control animals treated survived, and the latter had significantly lower $P\bar{v}O_2$, i.e., less adequate tissue oxygenation (86). In a model of surgical hemodilution to a hematocrit of 20%, the PFC provided 40% of the O_2 consumption (63). Clinical efficacy of *Oxygent* was demonstrated in a Phase 3 clinical study in surgical patients. (See section on Augmented Acute Normovolemic Hemodilution (A-ANHSM).

Using *Oxygent*, further demonstration that small doses of PFCs can contribute significantly to tissue oxygenation (26, 32, 33, 45) includes: increase in maximal O_2 consumption by an isolated working skeletal muscle in the presence of PFC; effective cardiac muscle function preservation in a canine model of low-flow coronary ischemia; sustainment of cardiac tissue oxygenation for a prolonged period following arrest of coronary perfusion of isolated rat hearts; improved myocardial O_2 delivery and aerobic metabolism during cold cardioplegic arrest of isolated rabbit heart; graded increase in $P\bar{v}O_2$ during cardiopulmonary bypass in dogs in response to graded increases in PFC dosing; preservation of cerebral function following experimental brain stem ischemia in dogs; significant increase in retinal O_2 tension and brain oxygenation in cats; improvement in the cat's primary visual cortex tissue pO_2 upon intravenous infusion of the emulsion; restoration of cerebral O_2 delivery in severely hemorrhaged rats; improvement of systolic function and reduction of myocardial edema and acidosis with PFC-supplemented cardioplegia in dogs that underwent CPB, global myocardial ischemia, followed by cold cardioplegic arrest, and eventually normothermic reperfusion; preservation of regional organ perfusion in myocardium, intestinal mucosa, liver, lung, kidney, and skeletal muscle; improvement of myocardial oxygenation and tolerance to low-flow ischemia (as found with

certain surgical procedures) in isolated rabbit hearts; improved tumor oxygenation and increased tumor radio- and chemosensitivity.

SAFETY

The acute toxicity of properly prepared PFC emulsions is low. The intravenous LD_{50} of Fluosol was estimated at 26–29 and 35 g PFC/kg body weight in rats for 20% and 35% w/v concentrated emulsions, respectively, indicating that the volume injected (130–145 and 101 ml/kg) may have had a part in these LD_{50} values (52). Similar figures were reported for *Perftoran* (43). For PFOB the LD_{50} reached 41 g/kg body weight when a 100% w/v emulsion (52 vol%) was administered to rats (87). No carcinogenic, mutagenic, teratogenic effects, or immunogenicity have been found for properly purified and formulated PFC emulsions. The anaphylactoid reaction observed with some patients with Fluosol (64) was determined to be due to complement activation by the poloxamer used as a surfactant in the formulation. It was no longer observed with the EYP-based emulsions (56, 65, 88).

The side effects observed in the clinic with the early 100% and 90% w/v concentrated PFOB formulations (56) and with Oxyfluor (63) consisted of early effects, during or shortly after infusion, including headache and occasional lower backache, and delayed effects (2–12 h), referred to as flu-like symptoms; e.g., fever, occasional chills and nausea (56, 75). These reactions, generally categorized as mild, were transient and fully reversible within 4–12 h. A transient, moderate drop (about 15%) in platelet count was seen about 3 days after dosing. Similar effects have been documented for parenteral fat emulsions and liposomes, indicating that these effects were likely related to the particulate nature of the emulsion.

The mechanism of the flu-like side effects was shown to be, for most part, related to the progressive clearance of the droplets from the blood stream. The effects are considered the natural consequence of macrophage activation during phagocytosis, which is accompanied by the release of products from the arachidonic acid cascade, including diverse prostaglandins and pyrogenically active cytokines (56, 63).

The magnitude and frequency of the particle-related side effects depend strongly on particle sizes (52, 57). Adjustments in the *Oxygent* emulsion formulation and processing parameters (and, in particular, the addition of PFDB, which helped reduce particle size and narrow particle size distribution) resulted in significant attenuation of the side-effect profile (57). During clinical safety

studies in conscious volunteers with the optimized 60% w/v *Oxygent* formulation AF0144, fever was less frequent than seen with an earlier formulation and seldom exceeded 1°C, and platelet count, although temporarily depressed with respect to baseline, remained within normal range (75, 89). In the normal volunteers, there were no effects on platelet function and coagulation parameters, complement activation, immunologic or allergic reactions, vasoconstriction or microcirculatory disturbances, no abnormal changes in liver function, pulmonary or renal function, or clinically meaningful effects on blood chemistry at the doses administered (90). No complement activation was found either with *Oxyfluor* (88). No emulsion-related serious adverse clinical events were reported in a subsequent Phase 2 efficacy study in orthopedic surgery patients (91).

PFCs have no capability to react with and scavenge nitric oxide, and clinical trials with EYP-based PFC emulsions have shown no perturbation of hemodynamics, increased vascular resistance and arterial tension, reduced cardiac output or heart rate. Cardiac output increased normally in response to hemodilution. Coagulation function, including bleeding times, were unaffected by the administration of *Oxygent* (89).

The observation that the lungs of rabbits given Fluosol or emulsions containing volatile PFCs, such as FX-80 or FDC, did not deflate normally at autopsy raised concerns about a possible toxic effect of these PFCs in the lungs (58). This phenomenon, which relates to increased pulmonary residual volume (IPRV) due to retention of air in the alveoli (92), is species-dependent and dependent on the PFC's vapor pressure. No such effect was reported for the patients who had received Fluosol, although it contained FDC. Addition of a small percentage of PFDB to PFOB in *Oxygent* further reduced the vapor pressure of the PFC phase to less than 8 torr, which sufficed to eliminate IPRV in most of the sensitive animal species (56).

PRINCIPAL INDICATIONS

Surgery

A recently defined, novel strategy for reducing the need for donor blood transfusions and increasing patient safety during surgery involves the use of an O₂ carrier in conjunction with acute normovolemic hemodilution in the so-called Augmented-ANH (or A-ANH) procedure (26, 91, 93). The A-ANH procedure (Fig. 5) consists first in collecting a portion of the patient's blood, usually 2 to 4 units, immediately before surgery begins. This blood is set aside in the operating room, and is replaced by a

Fig. 5 In the augmented acute normovolemic hemodilution (A-ANH) procedure, two to four units of blood are withdrawn from the patient just before undergoing surgery and are replaced by a volume-expanding solution. When, during surgery, the need for transfusion is determined, a PFC emulsion is administered instead of RBCs, thus preventing tissue hypoxia from occurring. When the hemoglobin concentration reaches a level that is considered unsafe, or at the end of surgery, the patient receives his/her own fully effective fresh blood back. The A-ANH procedure is expected to provide increased safety and reduced exposure to allogeneic blood, and to help reduce blood shortages. (Courtesy of Alliance Pharmaceutical Corp.)

plasma expander to maintain constant circulatory volume. When, during the surgery, the patient would normally be transfused, the patient receives the O₂ carrier instead. Tissue oxygenation thus remains in safe control and, by operating at a lower hematocrit, fewer RBCs are lost during surgical bleeding. If the hemoglobin reaches a level that is deemed too low, or at the end of the surgery, the patient receives back his or her own safe, fresh, and fully functional blood.

The A-ANH procedure is expected to allow more profound hemodilution without impairment of tissue oxygenation, resulting in reduced exposure to allogeneic blood transfusion (26, 40, 93, 94). Because the emulsion enables the physician to perform ANH in a safer and more effective way, it should help make ANH available to a broad population of surgical patients (about 6 million a year in the United States). Additionally, by allowing each patient to be his or her own donor, this method also has the potential to improve the overall availability of blood and substantially relieve banked blood shortages. This strategy has become a primary target indication for O₂ carriers.

Clinical trial data with *Oxygent* confirmed the expectations. Even a low 0.9 g/kg dose of PFC, administered after ANH, allowed P \bar{v} O₂ (85) values to remain at or above predosing levels while Hb levels decreased substantially due to surgical blood loss. Multicenter randomized Phase 2 trials involving patients undergoing elective surgery with ANH, determined that a 1.8 g/kg dose of PFC was significantly more effective than

fresh autologous blood (which is more effective than 2,3-DPG-depleted stored RBCs) at reversing physiological transfusion triggers (40, 75, 91). Use of the PFC emulsion also substantially delayed the need for transfusion of the stored autologous blood. The benefit of reduced viscosity on cardiac output was fully preserved. An hemoglobin equivalency for PFOB was established from the clinical data to be about 1.5 g of hemoglobin for 1 g of PFOB in the above conditions of use (47). Alliance Pharmaceutical Corp. recently announced that its Phase 3 clinical study with *Oxygent* in surgical patients in Europe (33 centers in 8 countries) was successful in reducing the need for donor blood transfusion. The intent of the study was to determine whether the use of *Oxygent*, administered according to the A-ANH procedure, would reduce the need for donor blood when compared to standard transfusion therapy. Statistically significant reduction in donor blood use was found in the entire study population. The target population consisted of those patients (86% of all patients enrolled) for whom a transfusion is most likely needed (i.e., experiencing modest to high surgical blood loss). In this population *Oxygent* provided highly significant avoidance ($p = 0.002$) or reduction ($p < 0.001$) of donor blood transfusion versus control patients receiving standard transfusion therapy. No safety issues were reported.

Cardiopulmonary Bypass Surgery and Neuroprotection

A-ANH with PFC emulsions is expected to have significant value in cardiopulmonary bypass (CPB) surgery (95, 96). Addition of the O₂ carrier to the solution that is used to prime the extracorporeal circuit should reduce the need for allogeneic RBC transfusion while increasing O₂ supply. Phase 3 clinical trials are currently underway in Europe and the United States in surgery patients with CPB support. In addition, because PFCs are able to dissolve nitrogen as well as oxygen, they could dissolve the tiny air bubbles that may be introduced in the CPB circuit and may cause microemboli. They could thus reduce the incidence and severity of the neurological deficits observed in a significant proportion of the patients undergoing cardiovascular surgery with CPB.

A Bridge to Transfusion

There are a number of instances where administration of a PFC emulsion could help bridge the time gap between a critical need for increased tissue oxygenation and transfusion of compatible blood, or between the time of transfusion and that when the transfused banked blood

becomes fully effective. Trauma is one such situation, in particular during the prehospital “golden hour” period that largely determines the outcome for the patient. During this period, blood is usually not available and transfused stored blood not yet fully operative. Fluorocarbon emulsions may provide a means of stabilizing the patient waiting for an intervention, and could therefore find their place in any ambulance or rescue vehicle.

Further Indications for PFC Emulsions (26, 32–34, 40, 34, 97–99)

Potential cardiovascular therapeutic uses for PFC emulsions, other than CPB, include treatment of acute myocardial infarction, cardioplegia, reperfusion, coronary angioplasty and preservation of donor hearts for transplantation. High O₂-delivery capacity, small particle sizes, and low viscosity may improve tissue perfusion and oxygenation. Treatment of cardiac arrest is also being explored.

Stroke is one of the leading causes of death in the industrialized countries. The brain is extremely sensitive to O₂ deprivation. In the case of vessel obstruction, the small size PFC droplets could improve perfusion and provide support to ischemic tissues by using smaller collateral vessels. Contrary to blood, the emulsions do not tend to have increased viscosity at low shear rate. Perfusion of the brain with PFC emulsions through the ventriculo-cisternal route is also being investigated.

Solid tumors, because of poor vascularization, generally contain hypoxic cancer cells that are resistant to treatment. PFC emulsions can deliver O₂ deep into tumor regions that would otherwise be hypoxic, thereby improving the response of tumor cells to radio and chemotherapy without compromising the tolerance of normal tissues.

Use of PFC-enriched perfusates has the potential for increasing the availability and quality of organs suitable for transplantation. Kidney, heart, liver, lung, pancreas, testis, and multiple organ blocks have been preserved using such preparations.

Various types of PFC-based contrast agents for diagnosis using X-ray computed tomography (CT), magnetic resonance (MR), and ultrasound (US) imaging have been investigated. PFC emulsions also allowed mapping O₂ in tissues by exploiting the ability of the paramagnetic O₂ molecule to perturb the ¹⁹F nuclear magnetic resonance signals.

Further potential applications for O₂-carrying PFC emulsions include treatment of sickle cell disease; use of intraperitoneal perfusion as an alternative to pulmonary oxygenation during certain forms of respiratory failure;

treatment of CO intoxication; treatment of decompression sickness; "total body washout" for removal of toxins, viruses, drug overdoses, etc.; treatment of acute pancreatitis; protection of the gastric mucosa against damage provoked by hemorrhagic shock; stabilization and control of animal models, organs, and tissues; and use as drug-delivery systems.

Medical Applications of Perfluorochemicals in Other Forms than Emulsions (72, 98, 99, 100)

PFC-stabilized gaseous microbubbles are being developed as contrast agents for ultrasound imaging. Externally applied PFC-filled pads are commercially available (*SatPad*[®], Alliance Pharmaceutical Corp.) that improve magnetic homogeneity, hence image quality, when fat saturation techniques are utilized during MR imaging. Neat PFCs are used as an ocular tamponade for treating complicated retinal detachments or managing the dislocated crystalline lens. Further potential applications include use in blood oxygenators; prevention of the bends by liquid breathing; treatment of ischemic ulcers; preservation of plant and animal semen, tissues and transplants; increasing growth rates of animal and plant cell cultures; and delivery of drugs to the lung. Fluorinated amphiphiles are critical components of a variety of colloidal and supramolecular systems with potential in drug delivery.

PROSPECTS

Although use of hemoglobin as an O₂ carrier for developing a blood substitute appears to be a *natural* approach and therefore attracted much interest and effort, an increasing body of experimental and clinical data indicates that the PFC approach has its advantages as well. These advantages include greater simplicity, chemical and biological inertness, and large contribution to O₂ consumption relative to O₂ content due to dissolution proportional to FiO₂, effective extraction and preservation of increased cardiac output following normovolemic hemodilution. The fact that PFC-based O₂ carriers do not rely on the collection of human or animal blood or on the genetic engineering of a mutant hemoglobin is another definite advantage. PFCs can be produced in virtually any amount to satisfy the needs. The emulsion manufacturing process being additive results in high yields. It is also very cost-effective. PFC emulsions are heat sterilizable, ready for use and have a long shelf life. They elicit no vasoconstriction or other

pharmaceutical activities that could potentially compromise O₂ delivery to tissues.

PFC emulsions, together with augmented acute normovolemic hemodilution potentially provide a straightforward means of better managing a patient's *own* fresh blood during surgery, thereby contributing to improved safety and relief from blood shortages. Blood substitutes are thus expected to profoundly change the practice of transfusion medicine.

Future research will certainly aim at further increasing emulsion stability, reducing side effects, prolonging circulation life, and exploring novel therapeutic indications for PFC-based O₂ delivery systems.

BLOOD SUBSTITUTES: HEMOGLOBIN-BASED OXYGEN CARRIERS

Deanna J. Nelson

BioLink Technologies, Inc., Cary, North Carolina, U.S.A.

INTRODUCTION

Successful allogeneic blood transfusion, one of the most important life-saving procedures of modern medicine, was first reported in 1818 (1). Its use grew steadily until the 1990s, when it peaked and reached a plateau. Today, more than 12 million units of packed red blood cells (RBCs) in the United States and at least 20 million red cell units worldwide are transfused into patients annually (2, 3). The chief indication for RBC transfusion is anemia, and the therapeutic goal is to increase oxygen delivery (4).

As transfusions began to occur in greater numbers, risks associated with this therapy began to be recognized. The hemolytic reactions that were a consequence of many of the early transfusions have largely been eliminated by blood typing and cross-matching. In contrast, the possibility of disease transmission by blood-borne pathogens, first recognized in the early 1940s, has not declined (5). Today, donated blood is tested for the presence of a broad spectrum of infectious agents, including hepatitis B and C, human immunodeficiency virus (HIV) 1 and 2, and human T-cell lymphotropic virus (HTLV) 1 and 2. In addition, blood may be contaminated with agents that are not monitored, including herpes viruses, such as cytomegalovirus or Epstein-Barr virus, parvoviruses, bacteria or parasites, such as *Yersinia* or *Trypanosoma cruzi*, respectively, or poorly characterized pathogens, such as those responsible for Creutzfeld-Jakob disease.

Other undesirable shortcomings of stored RBCs include an increase in the oxygen affinity of the intracellular hemoglobin due to losses in intracellular effectors (primarily 2,3-diphosphoglycerate) (6). Adverse changes in RBC shape and deformability, associated with the loss of cellular adenosine triphosphate (ATP) during storage, further compromise the RBC capability to deliver oxygen, because poorly deformable RBCs can become entrapped and impede local blood flow in the microcirculation (7, 8). In addition, immunogenic reactions, particularly those that occur after multiple transfusions or the transfusion of multiple units of allogeneic RBCs, are of continuing concern (9). Finally, several studies have shown depressed immune function post-transfusion of RBCs; i.e., patients with different tumors had a shorter disease-free survival and a higher incidence of recurrent or metastatic cancers or

a higher rate of postoperative infections after homologous blood transfusions (10–12).

A number of forces have combined to stimulate the development of fluids, so-called blood substitutes, that could be used in place of allogeneic blood. For example, the pressing need for the ready availability of a completely compatible “blood” has been recognized for many years (13) and continues to be important today. The observation that there are ischemic states where blood volume is not depleted but a requirement for the restoration of oxygen delivery is present, has focused attention on oxygen-carrying fluids that might be infused where RBC transfusion clearly is not indicated. All of these factors, together with a perceived commercial potential, have combined to promote the development of blood substitutes.

The term “blood substitute” is, however, a misnomer. Blood has dynamic, metabolic, regulatory, coagulation, and immunologic functions not mimicked by the plasma volume expanders or electrolyte solutions that are used clinically for volume replacement following blood loss. Nor are these properties embodied in the two classes of oxygen-carrying fluids, hemoglobins and perfluorocarbons, that are being developed as proposed alternatives to one component of blood, the red cell. As a result, it is widely recognized that the therapeutic use of blood and its various components will continue to expand; consequently, voluntary donations and advances in transfusion therapy must be continued in order to meet clinical needs.

This review will focus on hemoglobin therapeutics, that is, those hemoglobin-based oxygen carriers under development to complement the oxygen-carrying properties of blood. Given this focus on the requirement that the fluid transport and deliver oxygen, the review neglects consideration and discussion of colloidal plasma expanders (e.g., albumin, dextran, gelatin, and hydroxyethyl starch) and electrolyte solutions [Ringer’s lactate (RL) solution, for example]. Selected properties of these resuscitation fluids are compared in Table 1.

HISTORICAL OVERVIEW

Over a century ago, hemoglobin (Hb), the protein in RBCs, was discovered to be the means of oxygen transport

Table 1 A summary comparison of the properties of blood, blood substitutes, and volume expanders

Property	Blood	Blood substitutes	Volume expanders
Volume expansion	Yes	Yes	Yes
Oxygen carrying capacity	Yes	Yes	No
Other therapeutic proteins	Yes	No	No
Therapeutic life	1–2 months	1–2 days	Hours (varies with dose and species)
Storage life	1 month	6–24 months	2 years
Changes during storage	Yes	No	No
Type specific	Yes	No	No
Viral inactivation	No	Yes	Yes
Size	Large	Small	Small
Viscosity	High	Low/moderate	Low

by blood (14). Thus, it is not surprising that preparations of this protein have been repeatedly evaluated as the active principal of temporary blood replacement solutions (15).

Human Hb, a typical mammalian Hb, is a protein made up of four polypeptide subunits—two α -chains and two β -chains. Each subunit contains a heme prosthetic group, consisting of a porphyrin ring and an iron ligand. In the form of Hb capable of reversibly binding oxygen, the iron is in its +2 oxidation state, the ferrous form, and is sequestered by the porphyrin ring within the protein. If the iron is oxidized to its ferric or +3 form, Hb is oxidized to methemoglobin (methHb), which is incapable of binding oxygen. The molecular weight of human Hb is about 64,500 Daltons, similar to that of bovine Hb, another widely studied mammalian Hb (10–12).

Whereas anecdotal results obtained with historically prepared Hb solutions were somewhat encouraging, it became apparent that purified Hb is rapidly excreted through the kidneys after intravenous infusion and does not effectively release oxygen to the tissues (16). The former results when, once outside the red cell, normal tetrameric Hb dissociates into dimeric subunits readily filtered through the kidney glomerulus. The inability to efficiently release oxygen to the tissues stems from the fact that purified, acellular human Hb assumes a conformation that binds oxygen with a higher affinity than Hb in RBCs. Human RBCs contain high concentrations of 2,3-diphosphoglycerate (2,3-DPG), an organic polyanion that binds to Hb in a manner such that the affinity of oxygen binding is decreased. Unfortunately, 2,3-DPG readily hydrolyzes during the storage of blood for transfusion purposes or is lost during Hb purification.

Analysis of these historical observations on the properties of purified native human Hb has led to the conclusion that Hb must be modified in order to be clinically useful. Generally, Hb modification achieves two goals: first, the oxygen affinity of the Hb is decreased, and

second, its intravascular retention is prolonged. Beyond these general objectives, however, there is little agreement. Historically, a plasma expander is expected to be highly hydrophilic, nontoxic, and nonantigenic, have a colloid osmotic pressure close to that of blood, have a viscosity compatible with physiological conditions, and be biodegradable or excretable, but with a sufficient half-life (17). In addition, the Hb should not cause a foreign-body reaction, should be immunologically inert, should not simulate the coagulation cascade, should not stimulate the complement system, and should neither stimulate nor depress other defense systems inside the body (18). However, these properties are insufficient to define the optimal oxygen affinity or molecular weight profile of a therapeutically suitable Hb. Other criteria, vague at the present time, include the appropriate balance between oxygen-carrying capacity and colloid osmotic activity of the Hb and the corresponding balance between the intravascular retention as a functional Hb and optimal metabolism of the oxidized Hb. Nor is there agreement on the maximum tolerable methHb content of a therapeutic Hb, although it is recognized that methHb levels greater than 10% may significantly reduce tissue oxygenation (19).

Historical results obtained with Hb solutions were also confounded by the fact that many of these preparations were impure. One common impurity was fragments of the red cell plasma membrane, denoted as “stroma.” This stromal detritus was subsequently shown to be responsible, at least in part, for the kidney toxicity frequently observed after Hb infusion (20). For this reason, stroma must be rigorously excluded from Hb preparations. In addition to removing a source of nephrotoxicity, rigorous stroma removal eliminates the blood type specific antigens, thereby enabling these purified Hb formulations to be administered to any patient without the necessity of blood typing or cross-matching.

Endotoxin contamination has been encountered frequently in Hb solutions. Historically, the production of Hb solutions low in endotoxin content has proven challenging, in part because much of the early work was performed in academic research laboratories that were not familiar with the techniques used in the pharmaceutical industry to prevent bacterial contamination of the process stream. In addition, Hb has been reported to bind endotoxin, making it even more difficult to completely remove once present (21). Therefore, the production of Hb solutions must be carefully designed to minimize the introduction of endotoxin into the process stream.

THERAPEUTIC HBS UNDER DEVELOPMENT

Hb Sources

Hb suitable for modification may be obtained from any one of a variety of natural and biotechnological sources. In terms of quantities available, mammalian red cells are the most useful source at the present time. Over 90% of the protein in a typical mammalian red cell is Hb, and the protein is readily isolated by lysis of the red cell membrane. Red cell-sourced Hbs in commercial development are isolated from either human or bovine red cells.

If the Hb is isolated from mammalian red cells, both freshly collected and stored red cells may be used as sources. The red cell membrane is the site of the primary deterioration that occurs in RBCs during storage for transfusion, whereas the quality of Hb contained within cells remains unchanged (22). As a consequence, the quality of Hb obtained from expired RBC units is high, and both freshly collected and expired but otherwise transfusable RBC units are suitable as Hb sources.

Genetic engineering has enabled production of Hb in microorganisms, transgenic animals, and plants (23). A mutant, cross-linked human Hb has been expressed in *E. coli* at a large scale (24). An Hb expression system in yeast has also been described (25). Human Hb has been expressed at high levels in both mice and swine (26). Clearly, the latter animal is one from which suitably high quantities of Hb could be obtained for commercial development.

Classes of Modified Hbs

At present, four classes of modified Hbs are under development: 1) intramolecularly cross-linked Hb; 2) conjugated Hb; 3) polymerized Hb; and 4) Hbs produced by a combination of these processes (Fig. 1).

Fig. 1 Types of modified Hb.

Hb may be intramolecularly cross-linked between the α - or the β -subunits of the protein by chemical or genetic engineering methods. For example, if a polyanionic cross-linking agent such as bis(3,5-dibromosalicyl) fumarate (DBBF) or 2-norformyl- pyridoxal 5'-phosphate is used, Hb is selectively cross-linked in the so-called DPG-binding site between the beta subunits. If this site is blocked by an unreactive polyanion, Hb may be selectively cross-linked between the epsilon-amino groups of the lysine-99 residues on the alpha subunits, as it is in Diaspirin Cross-Linked Hemoglobin (DCLHb; Baxter). Alternatively, by insertion of the appropriate DNA constructs, the expressed Hb is intramolecularly cross-linked between the amino- and carboxyl termini of the alpha subunits. Intramolecularly cross-linked Hbs have a molecular weight and structure nearly identical to the native Hb from which they are derived.

Hemoglobin may be conjugated with a wide variety of polymers, including monomethyl polyethylene glycol (MPEG),^a dextran, and inulin. Conjugation is effected specifically only if the polymer is monofunctionally activated, i.e., if there is only a single site for reaction with Hb. However, multiple polymer chains may be attached to a single Hb molecule. Attachment typically occurs to the ϵ -amino groups of lysine residues located at the surface of the protein, although other amino acids (histidine, arginine, cysteine, or tyrosine, for example) may be modified under specific reaction conditions or through the use of specific reagents. Because the reaction is typically

^aAlthough MPEG is generally viewed as a monofunctional reagent, most commercial MPEGs are contaminated with bifunctional polyethylene glycol (PEG). Therefore, both conjugated and polymerized Hbs are obtained from modification reactions using these reagents.

Table 2 Products in commercial development and their potential clinical applications

Company	Modified Hb	Clinical study focus
Apex Biosciences Inc. (USA)	PEG-conjugated human Hb (Hb-PHP)	Septic shock
Baxter Healthcare Corp. (USA)	Modified rHb	No current trials ^a
Biopure Corp. (USA)	Glutaraldehyde-polymerized bovine Hb (HBOC-201 or Hemopure™)	Surgery
Enzon Corp. (USA)	PEG-conjugated bovine Hb (PEG-Hb)	Adjunct to radiation therapy
Hemosol (Canada)	Oxidized raffinose-polymerized and cross-linked human Hb (o-Raff-Hb or Hemolink)	Orthopedic or cardiac surgery; use as an adjunct to erythropoietin in treatment of chronic renal failure
Northfield Laboratories (USA)	Pyridoxalated, glutaraldehyde-polymerized human Hb (PolySFH-P or PolyHeme)	Trauma, surgery

^aDevelopment of DCLHb, an intramolecularly cross-linked human Hb, was discontinued in 1998.

one of surface modification, the modified Hbs are sometimes described as “decorated” Hbs. The conjugated Hbs obtained by this type of modification typically have a range of molecular weights defined by the molecular weight of the conjugating reagent and the number of molecules of that reagent conjugated to the protein. In addition, if the conjugating reagent is contaminated with precursors having more than one reactive site (as may be true of MPEG, for example), polymerized Hbs may constitute a part of the final product.

Likewise, Hb may be polymerized by a wide variety of reagents; the most widely used is glutaraldehyde. Other polymerization agents include oxidized adenosine, oxidized raffinose, and bifunctional, activated PEGs. A typical polymerization agent is bifunctional, offering two sites for reaction. Attachment occurs to the ϵ -amino groups of lysine residues located at the surface of the protein. The modified Hbs obtained by polymerization are polymers with about 2–10 Hbs linked linearly. Although branched polymers may also be obtained, the use of short polymerization agents significantly favors linear polymerization of Hb. In addition, during the reaction, Hb may be surface-modified (“decorated”) by the polymerization agent. The polymerized Hb products are mixtures of decorated polymers, ranging in molecular weight from the mass of the native Hb to 10-fold multiples of that molecular weight. (Higher molecular weight entities tend to be unstable and precipitate from solution.)

Finally, modified Hbs may be produced by a combination of these processes. For example, human Hb

may be cross-linked and then conjugated to another macromolecule, or the Hb may be cross-linked and then polymerized. (Although the processes may be reversed, cross-linking first ensures that tetrameric Hb will be further modified.)

The information in Fig. 1 and Table 2 illustrates the various approaches used by manufacturers of therapeutic Hbs now in clinical trials.

Formulation

Modified Hbs are most frequently formulated in electrolyte solutions iso-osmotic with human plasma. The Hb concentration typically is in the range of about 5–15%. Among the vehicles used in the formulation of the current generation of Hb therapeutics are phosphate-buffered saline, Ringer's acetate, and RL solution. Formulation in bicarbonate buffer has also been reported (27).

The effects of other additives, particularly anti-oxidants, have been investigated in an effort to extend the storage stability of the therapeutic Hb (28). However, not all reducing agents can reduce Hb, and some may even act as Hb oxidants. For example, ascorbate and glutathione, two of the more widely employed pharmaceutical anti-oxidants, are effective anti-oxidants only for deoxyhemoglobin solutions and are oxidants when Hb is oxygenated. Moreover, some anti-oxidants or reducing agents are unsuitable for therapeutic use or may be effective only within a pH range that is not tolerated well

physiologically, or are toxic in the concentrations required to show effectiveness as an anti-oxidant.

Encapsulation in liposomes or polylactide nanoparticles has been studied as a means for increasing the Hb concentration of a formulation while maintaining a low colloid oncotic pressure, prolonging the lifetime in the circulation, and reducing direct Hb exposure to cells and tissues in the body. To date, Hb encapsulation has met with limited success. Data from early studies of liposome-encapsulated Hb (LEH) focused attention on the shortcomings of these preparations as follows: immune system suppression, complement activation, difficulties in controlling endotoxin contamination, and the relatively low (1–2 g/dl) Hb concentration typically captured in liposomes (29). More recent work has benefited from the progress in liposome encapsulation made in other areas (30). Although low Hb-encapsulation efficiency remains an issue, several groups have demonstrated that improved encapsulation technology (31), coupled with surface modification of the liposome with PEG, further increases the circulation persistence of the LEH, presumably by decreasing recognition and reticulo-endothelial system (RES) uptake (32–36). Moreover, the ability to co-encapsulate systems for preventing Hb oxidation or effecting metHb reduction offers the advantage of prolonging the circulation of a functional oxyHb (37). Finally, the recognition that PEG-modification also allows for greater drug delivery to tumors may redirect clinical applications of LEH to this area as well as to resuscitation (38).

Packaging and Storage

Gradual Hb oxidation to metHb is a stability-limiting parameter during long-term storage of modified Hb solutions. In contrast, both native and modified Hbs are remarkably stable when stored deoxygenated or completely ligated by carbon monoxide. Moreover, following exposure to room air, deoxyhemoglobin is rapidly oxygenated. Consequently, most firms developing therapeutic Hbs store their preparations deoxygenated. Alternatively, an oxygenated Hb solution may be stored frozen; storage at -80°C ensures long-term stability. Likewise, the protein may be lyophilized and reconstituted at the time of use.

Although glass containers are very suitable for Hb packaging, flexible plastic containers constructed from materials such as poly(ethylene-vinyl acetate) (EVA) are most widely used. The plastic packaging material must be carefully selected. Hemoglobin, like other proteins, is lipophilic and can facilitate extraction of low molecular

weight lipophilic substances, such as the plasticizers used in poly(vinyl chloride) containers.

Technical Issues Associated with Commercial Production

When mammalian red cell Hb is used as the raw material for production of a modified Hb, the requirement for the minimization of plasma proteins and red cell stroma is a rigorous and general one. Some manufacturers meet this requirement by extensive red cell washing to reduce contamination by residual plasma, controlled lysis, and careful filtration of the hemolysate, followed by ultrafiltration. Other manufacturers add a chromatographic purification step to this procedure. Published data indicate that the phospholipid content of the so-called “stroma-free” Hb resulting from either process is very low ($<2\text{ }\mu\text{g/ml}$) (39–41).

A second issue associated with the commercial production of modified Hb from mammalian red cells is the exclusion of endotoxin contamination from the process stream and the product. Once introduced, endotoxin contamination is difficult to eliminate and causes a pyrogen response or a more severe, adverse effect in humans. Several chromatographic methods have been proposed as means for endotoxin removal (e.g., DEAE-Sephacrose or commercial affinity resins such as DetoxigelTM or Acticlean EtoxTM), but demonstrations are lacking as to their effectiveness for endotoxin removal sufficient to completely eliminate LAL-reactivity in Hbs produced at commercial scales (42).

Another microbiological purity issue that has been associated with human blood is the possibility of adventitious contamination with viral pathogens. Likewise, if animal blood is used as the red cell source, a spectrum of viruses have been identified as potential contaminants and possibly as zoonotic agents that may be infectious to humans (43). Therefore, in addition to the careful control of the blood used as the Hb source, the process for Hb solution preparation should employ robust virus inactivation and removal steps to reduce the risk of disease transmission.

When genetic engineering is used to produce the therapeutic Hb, three challenges present potential limitations to utility. First, the production scale itself presents a significant challenge. A second challenge is related to the expression system and its current limitations; and third, bacterial endotoxins or other pyrogens must be removed.

Genetic engineering enabling expression in microbial systems has been used successfully to produce proteins having annual production requirements of a few tons or

less. However, annual production requirements for a therapeutic Hb will likely reach thousands of tons following commercialization. Thus, matching the production capabilities to commercial requirements is a major challenge.

Enhancing expression efficiency of the desired Hb is a second challenge to be addressed for therapeutic Hb production (44). At present, the typical biotechnological process incorporates microbiological expression of each of the requisite globin proteins and insertion of preformed heme into the protein subunits. (Hemin isolated from bovine Hb is added to the growth medium in order to provide adequate amounts of heme.) In many expression systems, recombinant α - and β -chains are produced with an extra methionine at their respective amino termini. Since the native *N*-terminal valine residues of the α - and β -chains are known to play important roles in regulating oxygen affinity, in interactions with allosteric effectors, and in the Bohr effect, the extra methionine or another mutation at these *N*-terminals can alter both the protein conformation and the functional properties of the recombinant Hb (rHb). Moreover, Ho has reported that as much as 25% of the purified rHb exhibits an incorrect conformation of the heme group in the β -chain (45). Whether enhanced endogenous heme production would eliminate this defect is not known. At present, however, microbiological heme synthesis may not be sufficiently efficient to permit its use in commercial applications.

Finally, if *E. coli* is used as the production system, the therapeutic Hb must be purified rigorously. Both elimination of all non-Hb proteins and elimination of endotoxins are stringent requirements, because the latter lipoproteins are recognized pyrogens. Extensive chromatographic purification is used to accomplish this.

Some key issues are common to the development of any practical modified Hb solution. For example, the propensity of this protein to oxidize must be addressed. In order to remain functional in the delivery of oxygen, the iron in the prosthetic heme group of Hb must be maintained in the +2 oxidation state. Therefore, processing and long-term storage conditions must minimize the formation of metHb. This is accomplished in a number of ways. Low processing temperatures are used as much as possible. In addition, some processing steps that expose Hb to particularly adverse conditions may involve conversion of (oxy)Hb to deoxyhemoglobin or carboxyhemoglobin, completion of the process step, and subsequent reconversion to (oxy)Hb.

Irrespective of the manner in which the therapeutic Hb is manufactured, there is a general requirement

for conformance with current Good Manufacturing Practices.

POTENTIAL THERAPEUTIC BENEFITS

Many historical expectations regarding the potential safety and efficacy of Hb-based oxygen carriers have been realized, and these proteins are being increasingly recognized as therapeutic hemoglobins (tHbs). For example, tHbs may be administered without blood typing or cross-matching and apparently do not activate the complement cascade in the recipient or elicit an immune response (46). (However, trials of tHbs produced from bovine Hb may require testing for existing antibodies in patients prior to Hb infusion.)

The properties of the current generation of tHb solutions (Tables 2 and 3) that are expected to contribute directly to clinical potency are the abilities to transport oxygen, redistribute blood flow, and support the maintenance of vascular volume. The ability to transport oxygen is likely to be beneficial as a consequence of three properties of a therapeutic Hb: 1) the favorable oxygen binding characteristics of the reduced heme groups; 2) the small size of an acellular Hb compared to that of a red cell; and 3) the low viscosity of some tHb solutions. Given these properties, a tHb is likely to perfuse microcapillary beds and areas where red cell perfusion has been restricted by partial blockage or severe constriction. Potentially, these properties will prove beneficial in the following clinical indications. The three primary and most widely recognized potential indications are discussed first, followed by other, more speculative uses of a tHb.

Reduction of Acute Global Oxygen Deficit

Other than blood itself, tHb solutions are the only colloidal plasma volume expanders that will transport sufficient oxygen to maintain life. In general, preclinical studies in a spectrum of animal models of hemorrhagic shock show tHb solutions restore mean arterial pressure (MAP), promote adequate tissue oxygenation, more effectively resolve base deficit and ischemic acidosis, and improve survival in the test animals receiving the Hb formulation. In contrast, test groups receiving electrolyte [e.g., Ringer's lactate (RL)] or colloid (e.g., hetastarch or albumin) solutions responded less positively (47–50). Consequently, the most widely investigated potential therapeutic applications of the current tHb formulations comprise studies in which a tHb solution is infused as a substitute for

Table 3 Acronyms used in this review

Therapeutic Hb	Manufacturer	Acronym
Pyridoxalated, PEG-conjugated Hb	Apex	Hb-PHP
Intramolecularly $\alpha\alpha$ -cross-linked human Hb	Baxter	DCLHb
Glutaraldehyde-polymerized bovine Hb	Biopure	HBOC-201
PEG-Modified bovine Hb	Enzon	PEG-Hb
Oxidized raffinose-cross-linked and polymerized human Hb	Hemosol	o-Raff-Hb
Pyridoxalated glutaraldehyde-polymerized human Hb	Northfield	PolySFH-P

transfusion of blood or packed red cells or is used as a hemodiluent.

Resuscitation from acute hypovolemia or hemorrhagic shock

Infusion of a tHb in resuscitation from acute hypovolemia or hemorrhagic shock, clinical indications where blood or packed red cells typically are transfused, constitutes one of three general categories of clinical indications recognized by the FDA (51). Clinical trials assessing the efficacy and safety of a polymerized human Hb, PolySFH-P (Poly-Heme; Northfield), in these indications are in progress. Data concerning their safety and efficacy in reducing acute global oxygen deficit are not disclosed until patient enrollment is completed and rigorous, multi-faceted analyses are performed. Thus, it is difficult to predict when summaries will be presented that confirm the expectations based on preclinical findings.

Preliminary reports suggest these tHbs may be of value in resuscitation following trauma or unanticipated hemorrhage, where the Hb solution could be infused as an immediate response to blood loss. Under these conditions, the tHb is a bridge to transfusion: data accumulated during transport, in the emergency room or recovery room, peri-operatively, or in the intensive care unit, enable broader assessment of the physiologic need for a subsequent blood transfusion.

For example, a recent report discusses the assessment of clinical utility of PolySFH-P as a resuscitation fluid following acute trauma or urgent surgery (i.e., aortic aneurysm repair, hepatic resection, portosystemic shunt, and hip replacement) (53). Forty-four trauma patients with an average Injury Severity Score of 21 ± 10 were randomized to receive red cells (control; $n = 23$) or up to 6 units (300 g) of PolySFH-P ($n = 21$) as their initial blood replacement. Investigators blinded to the treatment made the decision to transfuse based on clinical signs, symptoms, and laboratory data, and the clinical circumstances. (PolySFH-P was given pre-operatively

and intra-operatively to both awake and anesthetized patients but only during the actual period of hemorrhage.) Samples were obtained before infusion, at the end of infusion, at 12 h, and at days 1, 2, and 3. Vital signs (temperature, blood pressure, and heart rate), liver function [aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin], amylase, and renal function (creatinine) were measured.

No important safety issues or significant adverse events related to PolySFH-P were observed, either during infusion or in the monitoring period that followed. It is noteworthy that a PolySFH-P infusion of 4.4 ± 2.0 units resulted in a plasma Hb of 3.9 ± 1.3 g/dl, which accounted for approximately 40% of the total circulating Hb. The plasma Hb concentration decreased to 2.2 ± 1.3 g/dl one-half day following infusion and to 1.4 ± 0.9 , 0.6 ± 0.6 , and 0.3 ± 0.3 g/dl on days 1, 2, and 3 postinfusion, respectively. No significant differences between groups were observed in temperature, MAP, heart rate (HR), and creatinine, documenting the absence of vasoactive properties, renal dysfunction, or fever because of PolySFH-P. Nor were differences in other measures of organ function observed, other than an increase in total bilirubin to concentrations in the range 2.4 ± 1.7 g/dl through the third day postinfusion. The total number of allogeneic red cell transfusions for the control group was significantly greater than that of the experimental group on days 1 and 3, post-infusion. Beyond 3 days post-infusion, all the PolySFH-P had left the circulation, and investigators transfused RBCs to address a further need for oxygen.

A subsequent Phase II study evaluated use of up to 10 units (500 g Hb) of PolySFH-P in treatment of acute blood loss (53). Early results (17 patients) suggested safety. Phase III trials in fifteen North American centers are assessing the therapeutic value of infusion of PolySFH-P in patients undergoing surgery for aortic aneurysm repair.

The efficacy of DCLHb, an intramolecularly cross-linked human Hb (Baxter) was assessed with respect to reducing or preventing the postoperative use of blood

transfusions (54). More than 1500 patients undergoing cardiac surgery were screened to enter this study. Of these, 209 were judged to be in need of transfusion after surgery, had met the study inclusion/exclusion criteria, and had signed informed consent. The patients were randomized to receive up to 3 units (a total of 750 ml) of 10% DCLHb or up to 3 units of packed RBCs within 24 h of surgery. Following this period, patients could receive additional transfusion of RBCs or other treatment as necessary. On the day of surgery, 59% of the patients treated with DCLHb did not require RBC transfusion. At day 7 after surgery, 19% of the DCLHb-treated patients had completely avoided a transfusion of RBCs. The mean number of units of RBCs transfused through 2 days postsurgery was significantly lower in DCLHb-treated patients than in controls ($p < 0.05$). After this period, there was no difference between the mean number of RBC units transfused in both groups. It was noted that DCLHb was well tolerated in this patient population and that there were no significant differences in morbidity or mortality between the groups.

In two other trials, one in the United States and the other in Europe, DCLHb was tested in trauma and hemorrhagic shock patients as an adjunct to the current therapies for enhancing oxygen delivery: fluids, blood, and operative intervention. In the multicenter, randomized, controlled, single-blinded efficacy trial conducted at 18 U.S. trauma centers from Feb 1997 to Jan 1998, patients with presumed or proven hemorrhage and persistent hypoperfusion were treated with DCLHb or normal saline (control) solution (55). Although there were no restrictions in the use of fluids, blood, or any other intervention prior to enrollment in this study, once enrolled, the patient received 500 ml of the treatment solution no later than 30 min after first meeting the entry criteria in the study hospital and within 60 min of hospital arrival. Critically ill patients who continued to meet entry criteria after treatment received up to an additional 500 ml of treatment solution during the 1-h infusion period. A key objective of the trial was a DCLHb-related reduction in the 28-day mortality in traumatic, hemorrhagic shock patients by 25%, i.e., from 40 to 30%. A reduction in 28-day morbidity or 48-h mortality and a normalization of 24-h lactate levels from base deficits of more than 15 mEq/l were corollary objectives. Of the 112 patients enrolled in the U.S. study before it was terminated in early 1998, 98 (88%) were infused with DCLHb or saline solution. At 28 days, 24 (46%) of the 52 patients infused with DCLHb died, and 8 (17%) of the 46 patients infused with the saline solution died ($p = 0.003$). At 48 h, 20 (38%) of the 52 patients infused with DCLHb died and 7 (15%) of the 46 patients infused with the saline solution died ($P = 0.01$).

The 28-day morbidity rate, as measured by the multiple organ dysfunction score, was 72% higher in the DCLHb group ($P = 0.03$). There was no difference in adverse event rates or the 24-h lactate levels. No subgroup analysis or covariate adjustment altered this mortality imbalance, nor did the 28-day multiple organ dysfunction score and the 24-h lactate clearance end points demonstrate a beneficial DCLHb effect. The study director noted that the absence of morbidity and perfusion marker improvements were due, in part, to the higher mortality rate in the DCLHb group, which limited the ability to measure morbidity independently using these two clinical markers. Moreover, it was noted that the study group believed it is not possible to conclude definitively that the mortality imbalance was due solely to a DCLHb-treatment effect. The study was terminated by the sponsor on March 17, 1998, based on the recommendation of the data monitoring committee. The concurrent second study in Europe was terminated a few months later.

Perioperative applications of therapeutic hemoglobins

Techniques for conserving the blood supply include not only substituting a tHb for blood itself, but also limiting the number of allogeneic blood transfusions in surgical patients through the use of autologous blood donations and intra-operative blood salvage. Late Phase II and Phase III trials are in progress, assessing the utility of two polymerized Hbs in these clinical applications.

No adverse effects were found during completion of a multicenter, Phase IIa trial in 18 orthopedic (hip replacement) surgical patients in which up to 500 ml of o-Raff-Hb (Hemosol), an oxidized raffinose-polymerized human Hb, were used for pre-operative hemodilution (56). A similar assessment is now being completed in cardiac surgical patients.

Four reports summarize clinical findings regarding similar hemodiluent applications of HBOC-201, a 13 g/dl solution of highly polymerized, purified bovine Hb (Biopure). The first of these evaluated the effects of low doses (ca. 0.4 g/kg) of HBOC-201 in 13 patients undergoing pre-operative hemodilution before elective abdominal aortic (repair) surgery (57) and the second, 12 surgical patients undergoing liver resection (58). After induction of anesthesia, autologous donation of a liter of blood, and hemodilution with either 1 or 2 L of RL solution, patients were randomly assigned to receive, within 30 min, a 3 ml/kg dose of either HBOC-201 or 6% hydroxyethyl starch (HES). Blood chemistry, co-oximetry, hematology, coagulation profiles, and immunological examinations were completed prior to surgery, on the day of surgery, on days 2, 3, 4, and 7 after the operation, on

the discharge day; 2, 3, 4 days postdischarge, and 3 months after operation. During surgery, monitored variables included invasive arterial and pulmonary artery pressures and arterial and mixed venous blood gases. The cardiac index (CI), systemic and pulmonary vascular resistance indices (SVRI and PVRI, respectively), oxygen delivery index (DO_2I), oxygen consumption index (VO_2I), and oxygen extraction ratio (O_2ER) were calculated using standard equations.

In general, the data indicated the low, single-dose administration of HBOC-201 was well-tolerated. However, in contrast to the patients receiving HES, patients who received HBOC-201 showed a progressive increase in MAP and SVRI and a significant decrease in CI, starting immediately after the beginning of the infusion; maximal changes were observed about 30 min after the infusion of the Hb solution ended. The investigators had anticipated clear signs of improved tissue oxygenation, as evidenced by an increase in arterial oxygen content and a maintenance or increase in DO_2I . However, the decreases in CI were sufficiently large that this calculated increase was not seen. The authors concluded that a 3 ml/kg dose of HBOC-201 was insufficient to augment the oxygen-carrying capacity of the blood.

Based on investigators' recommendations, the effects of increasing doses of HBOC-201 were assessed in two subsequent studies (59). After the induction of anesthesia, collection of 1 L of blood, and the infusion of 1 L of RL solution, 24 patients (12 in each study) were randomly assigned to receive, within 30 min, a 6.9- or 9.2-ml/kg dose of either HBOC-201 or 6% HES. (Patients infused with Hb received either 0.9 or 1.2 g Hb/kg, respectively.) Then, patients received an additional 500 ml of RL solution to maintain intravascular volume. As before, patient data relative to systemic and pulmonary arterial pressures and arterial and mixed venous blood gases were used to calculate hemodynamic and oxygen transport indices. The autologous blood withdrawn for preoperative hemodilution was reinfused intra-operatively after aortic unclamping.

In these two studies, as in the preceding ones, the infusion of HBOC-201 was associated with sizeable increases in SVRI (121 and 71%, respectively) and PVRI (70 and 53%, respectively). A concomitant influence on cerebral hemodynamics was not detected (60). Hemodilution with HBOC-201 increased the plasma Hb concentration to as high as 3 g/dl—Hb concentrations sufficient to maintain the arterial oxygen content at levels significantly higher than hemodilution with HES. However, the advantage of a greater oxygen-carrying capacity was offset by the increases in SVRI and PVR, and the resulting, sizeable decrease in CI. Although whole-body oxygen

consumption was maintained by increased oxygen extraction, in the absence of evidence of increased tissue oxygenation, the increase in oxygen consumption was viewed as a compensatory response to the decreased oxygen delivery, rather than a marker of enhanced unloading of oxygen. In terms of hemodynamics and oxygen transport, hemodilution with HBOC-201, either in low or clinically relevant doses, provided no apparent benefit over hemodilution with HES.

If a tHb is used perioperatively, studies must be completed to address concerns that cell-free Hb could alter red cell fragility or that shear forces typically found at the air/fluid interface of a cell-saving device could alter the structure of the tHb. To this end, 16 blood units were collected from healthy volunteers into CPD (blood preservation) solution and diluted with either HBOC-201 (1500 mg/dl; $N = 10$) or normal saline (equivalent volume; $N = 6$) (61). Automated, interoperative blood salvage was mimicked by suctioning the units into the reservoir of an autologous blood salvage system and processing the resulting solution. (The unit was operated manually, because the optical sensor that monitors the interface of red cells and supernatant in the centrifuge bowl of the unit responded to the red color of the bovine Hb in the supernatant and initiated the wash cycle prematurely and inappropriately.) Samples were analyzed for the concentration and molecular weight distribution of plasma hemoglobin and red cell morphology presalvage and following processing and washing. Five of the HBOC-201 units underwent a second 1000 ml wash. As a result of processing, the plasma Hb concentration of the HBOC units decreased from 1311 ± 265 mg/dl prior to "salvage" to 27.8 ± 19.6 mg/dl afterwards. (Processing the solution a second time further reduced the plasma Hb concentration to 6.5 ± 2.2 mg/dl.) Exposure to HBOC-201 did not alter red cell or platelet morphology, either pre- or postprocessing. Moreover, processing the HBOC-containing solution did not alter red cell fragility.

Hemodilution with a tHb as a part of cardiac surgery using cardiopulmonary bypass offers additional opportunity for conserving autologous blood. With the onset of bypass, a portion of the autologous blood volume could be collected via the venous cannulae and stored in a "set aside" reservoir. Simultaneously, a tHb solution could be included in the pump "prime" to replace the volume and oxygen-carrying capacity of the "set aside" erythrocyte mass. As a result, blood loss during the operation would include a lower percentage of the original erythrocyte mass, leading to net conservation of the autologous erythrocyte mass. After completion of cardiopulmonary bypass, the stored autologous whole blood could be returned to the patient with its associated clotting function,

thus contributing to decreasing homologous blood requirements. Additionally, setting aside a significant part of the autologous blood volume just before bypass may preserve platelet function.

Neya et al. studied the properties and stability of HBOC-201 in the bypass environment (62). One test preparation consisted of HBOC-201 solution diluted 1:1 with normal saline, and the second comprised 500 ml of blood added to 500 ml normal saline and 1 L of the HBOC-201 solution. Two liters of each test solution, warmed to 37°C, were evaluated in two types of cardiopulmonary bypass circuit models—a bubble oxygenator with an integral reservoir (BO; $n = 5$ preparations) and a membrane oxygenator/venous cardiectomy reservoir (MO; $n = 5$ preparations). A 50-ml sample of each diluted HBOC, oxygenated for 3 min in the bypass circuit and then stored at 37°C for 5 h, served as a control. Extracorporeal circulation in a continuous loop circuit was maintained at 2 L/min throughout the 5-h experiment. Samples were obtained after 30 min of bypass and hourly, thereafter, for determination of THb, metHb, the size-exclusion chromatographic and oxygen-binding profiles of the plasma Hb, and infusate pH. (Bicarbonate was added, as needed, to maintain physiological pH.) The Hb concentration did not change throughout the experiment. However, the MetHb content increased in all groups not containing RBCs and in the control from an initial value of about 3% to values of 22–28% at the end of the 5-h experiment. After 2–3 h circulation, the time required for most bypass surgeries, the metHb content was 15–20% in these HBOC-201 solutions. As McGown et al. found (63), RBCs significantly attenuated the rate and extent of Hb oxidation; in the presence of red cells, the plasma metHb content was about 8–10% after 2–3 h circulation and about 12% at the end of the experiment. As expected, increases in metHb content decreased the P_{50} value of the tHb (64).

In summary, the use of tHb solutions to counter acute hypovolemia and concurrent global ischemia attendant to trauma or surgery has met with widely divergent results. The reports available at the time of this writing suggest that when limited volumes of either DCLHb or PolySFH-P are infused in surgical patients, the infusion is tolerated well. Moreover, tHb infusion may reduce the requirement for blood transfusion. In contrast, when larger volumes of these tHbs are administered, only PolySFH-P continues to show potential utility in this indication. Development of DCLHb was terminated after unusually high mortality was observed in some trials.

Likewise, clinical assessment of the use of tHb solutions as a hemodiluent continues. If therapeutic benefit is confirmed in larger numbers of patients and

efficacy is shown, it is reasonable to anticipate regulatory approval and clinical acceptance.

Normalization of Hemodynamics and Tissue Oxygenation in Septicemia

Sepsis and its complications—hypotension, shock, and multiple organ system failure—represent a significant cause of mortality among hospitalized patients (65). Moreover, recent studies in a rodent septicemia model suggest that transfusion of stored red cells fails to effect acute improvement in tissue oxygenation in septic animals (66). The effects of tHb solutions have been assessed in a variety of animal models of septicemia (67–69) and in patients. The studies described below used specific tHbs. However, if the restoration of both adequate hemodynamics and tissue oxygenation is key to clinical utility in this indication, it is likely that similar results will be observed following the infusion of other tHbs that have these properties.

Clinical studies of the safety and efficacy of Hb-PHP (Apex) as a septicemia therapy are continuing. In a Phase I/II open label, ascending-dose study, patients with volume-refractory, vasopressor-dependent shock secondary to sepsis or presumed sepsis received a bolus infusion of Hb-PHP (25, 50, or 100 mg Hb/kg body weight) over 30 min and were observed for cardiovascular changes and adverse effects (70). Hb infusion was well tolerated and permitted a decrease in vasopressor utilization while maintaining an increasing MAP. No adverse effects on pulmonary, cardiac, renal, or hepatic functions have been noted at this dose level; Hb-PHP infusion increased SVR and decreased HR. These results supported further study of Hb-PHP in this indication.

In a subsequent Phase I/II study that allowed for dose escalation and extended duration of dosing, patients with shock secondary to sepsis or presumed sepsis received a dose of Hb-PHP of 160, 320, 640, or 2560 mg Hb/kg body weight (70). Dosing was initiated at a rate of 10 mg Hb/kg/h and increased in increments of 10 mg/kg/h at 15 min intervals to a maximum rate of 20, 40, or 80 mg Hb/kg/h for the lowest, middle, or two highest doses, respectively. At the highest dose, dosing was stopped if shock resolved (i.e., MAP >70 mm Hg without vasopressor). The dose rate was determined by titration to hemodynamic effect (i.e., the standard of care guideline of >70 mm Hg). Again, Hb-PHP infusion was well tolerated. The increased MAP and SVR observed following Hb infusion permitted a decrease in vasopressor utilization. The results supported a proposal that Hb-PHP be indicated for the treatment of shock associated with systemic inflammatory response syndrome (SIRS) in

fluid-refractory, pressor-dependent patients. A Phase III pivotal trial is planned.

Likewise, the hemodynamic effects of DCLHb (an intramolecularly cross-linked human Hb; Baxter) in 14 critically ill patients were evaluated in a prospective, observational study (71). All of the subjects required vasopressor therapy to maintain adequate MAP and had secondary organ dysfunction prior to DCLHb treatment. Following a decision by the investigator to infuse, boluses (100 ml) of DCLHb were given up to a maximum of 500 ml. Each infusion was separated by 60–90 min. Hemodynamic parameters, norepinephrine and inotropic requirements, arterial and mixed venous blood gases, and urine output were monitored, and biochemical and hematological analyses were made before DCLHb administration and at multiple times up to 72 h postadministration. The main end-point employed to assess the efficacy of DCLHb as a vasopressor was maintenance of the MAP at approximately pre-infusion values concomitant with a reduction in norepinephrine requirements. This objective was met, and reductions in norepinephrine requirements were maintained at 24, 48, and 72 h ($p < 0.01$ at all time points). Thus, even in these critically ill patients, whose prognosis of survival was very poor, DCLHb seemed to have a beneficial effect.

Use as an Adjunct to Cancer Treatment

Local effects of a tHb comprise the second of three general categories for indications recognized by the FDA (51). For example, the concomitant use of a tHb and a cancer therapy, such as ionizing radiation or chemotherapeutic agents, potentially has two benefits for the patient. First, cancer patients are usually anemic, and evidence has been presented that anemia is an important prognostic factor. Increasing Hb levels into the normal range can improve prognosis and treatment outcome (72, 73). Second, the small size (relative to a red cell) and excellent oxygen delivery capabilities of a tHb have the potential to improve tumor oxygenation, a factor which has been associated with increased tumor cell killing and delays in tumor growth following radiation or chemotherapy. Moreover, the Hb may be a source of heme to promote hematopoiesis (see below).

Although clinical study data have not yet been reported, preclinical studies in rodent models suggest that the administration of tHbs may demonstrate many of these benefits. For example, the effects of PEG-Hb on tumor oxygenation and response to chemotherapy were monitored in a study in which two rodent models of solid tumor cancer were used (74). When a 6 ml/kg (360 mg/kg) dose of 6 g/dl PEG-Hb solution was administered to rats bearing

the 13762 mammary carcinoma immediately prior to measurements of tissue oxygenation, the level of hypoxia in the tumor was significantly decreased, particularly when the animals were exposed to an oxygen-enriched atmosphere. Similar observations were made when the measurements were made 24 h after the administration of cyclophosphamide, melphalan, taxol, or cisplatin—chemotherapeutic agents that render the tumors severely hypoxic. Likewise, the co-administration of a 6 ml/kg dose of PEG-Hb to mice bearing the EMT-6 murine mammary carcinoma immediately prior to the administration of cyclophosphamide, adriamycin, 5-fluorouracil, 1,3-bis (2-chloroethyl)-1-nitrosourea (BCNU), or taxol on each of 3–5 days of treatment (depending on the chemotherapeutic agent) increased the effectiveness of tumor cell killing, delayed tumor cell growth, and increased the response of the metastatic disease without changing the toxicity to the bone marrow, as monitored by changes in the colony stimulating activity (CFU-GM). Taken together, the authors concluded that further investigation of PEG-Hb as an oxygen delivery agent in oncology is warranted.

In a parallel study, it was found that the administration of an Hb solution decreases hypoxia and increases radiation response in a rat mammary carcinoma model (73, 75).

In addition to these three applications, more exploratory studies are assessing the use of tHbs for clinical indications where blood typically is not used. Several of these applications are described below.

Support for Hematopoiesis/Erythropoiesis

Hematopoiesis is the process of blood cell production that takes place in the bone marrow. Through a complex series of regulatory events, stem cells are differentiated into various types of cells, including red blood cells. Stem cell differentiation is responsive to exogenous stimuli and can be upregulated to resupply a deficient cell population. However, only a limited number of therapeutics (iron, hemin, or erythropoietin, for example) can stimulate Hb-replete red blood cell formation. Recognition of the poor bioavailability of many iron compounds or hemin compositions and the improved safety profile of a tHb relative to unmodified Hb has renewed the interest in Hb administration as a stimulant for red cell production first shown in the 1920s. The two studies described below reference the use of specific Hbs. However, it is likely that many other tHbs will provide support for hematopoiesis.

A recent report summarized the effect of administration of a recombinant Hb, hrHb 1.1, on *in vivo* hematopoietic recovery in rodent models from azidothymidine (AZT)

toxicity (77). The results suggest that this Hb can alleviate AZT toxicity in normal and immunodeficient mice and that it may be clinically useful in preventing severe bone marrow depression brought about by various drugs or agents, such as AZT. Similarly, Lutton et al. have reported the hematopoietic effects of 50 ml infusions of 6% β - β cross-linked human and bovine Hb (DECA-Hb and XLBV-Hb, respectively) and noncross-linked (HbA) into rabbits following a 50 ml ear-bleed (78). All rabbits receiving DECA-Hb or XLBV-Hb tolerated the Hbs well, whereas 50% of the animals transfused with similar doses of noncross-linked HbA died. Analysis of peripheral blood and bone marrow BFU-E and CFU-GM production 2 days following Hb-infusion revealed no significant variation in the generation of BFU-E and CFU-GM numbers for each cross-linked Hb group, but significant reductions were observed in the HbA group.

Approval has been obtained for Phase II trials in chronic renal failure patients to use o-Raff-Hb (Hemosol) as an adjunct to erythropoietin (79). To date, no preliminary reports are available.

Maintenance of Tissue Oxygenation Resulting from Focal Ischemia

Oxygen deprivation follows when blood flow is compromised by a local, temporary circulatory blockade that may occur naturally as a result of stenosis, stroke, or a myocardial infarction (heart attack) or may accompany therapeutic interventions, such as percutaneous transluminal coronary angioplasty (PTCA). Packed RBCs are not useful for restoration of oxygen delivery in these situations, because they are too large to traverse the constricted vessels or too viscous and fragile to be pumped through a perfusion balloon catheter. A number of preclinical studies in this area are summarized below.

Cerebral ischemia

In patients at risk for focal cerebral ischemia, hemodilution has been proposed as a prophylactic and resuscitative therapy to ameliorate brain injury. The rationale for hemodilution therapy is based on two facts: 1) blood viscosity decreases when blood is diluted with many crystalloid and colloid solutions; and 2) an inverse correlation exists between blood viscosity and cerebral blood flow (CBF). However, the beneficial effect on viscosity by hemodilution with nonoxygen-carrying fluids is countered by a loss in oxygen-transport capacity. A tHb, by decreasing viscosity while maintaining oxygen delivery capacity, theoretically may improve oxygen delivery to ischemic areas of the brain, compared to the oxygen delivery achieved with typical clinically utilized

intravenous solutions. This hypothesis has been tested in several animal models of cerebral ischemia and ischemic neuronal damage (80, 81).

Cole et al. have performed several investigations using an instrumented, spontaneously hypertensive rat model to evaluate the therapeutic effect of DCLHb on focal cerebral ischemia (82–85). In these studies, middle cerebral artery occlusion (MCAO) followed by 10–90 min of ischemia resulted in consistent ischemia in both cortical and subcortical tissue. In both MCAO models, Cole observed that hemodilution with DCLHb augmented CBF and decreased infarct volume in a dose-dependent manner. Moreover, infarct-size reduction was greater and brain edema was less when the blood pressure was allowed to increase. Because the data suggested that in the ischemic brain a reduction in viscosity is the predominant mechanism for a hemodilution-induced increase in CBF, the effects of dilution with DCLHb were compared to those of like doses of oncologically matched albumin. The data demonstrated that in these models of cerebral ischemia, DCLHb decreased ischemic brain injury more proficiently than did albumin. Moreover, since the volumes of hemodiluent that may be used are limited, the observation that 20 g/dl DCLHb performed better than 10 g/dl DCLHb suggested that a hyperoncotic oxygen-carrying hemodiluent, such as 20 g/dl DCLHb, may be preferable to a relatively normo-oncotic fluid.

There is some evidence, however, that the potential utility of a tHb as a hemodiluent and tissue-oxygenating solution may be dependent on the structure and properties of that tHb. For example, the results of a study of the effects of partial blood replacement with pyridoxalated Hb polyoxyethylene conjugate (PHP) solution (Ajinomoto) in a gerbil model of transient cerebral ischemia suggested that PHP solution holds less promise as a clinical treatment for this type of focal ischemia than does DCLHb (86).

Therapeutic Hbs such as DCLHb potentially are unique hemodiluents in that in addition to reducing viscosity, cerebral ischemic injury may also be reduced by the maintenance of oxygen delivery by the tHb and by the inactivation of nitric oxide (NO) (87). This hypothesis was supported by the results of a study of cerebral ischemic injury in rats in which the effects of DCLHb infusion were compared to those of DCLHb infusion with L-NAME (an NO synthase inhibitor) or L-arginine (an NO synthase substrate) (88). It was found that the beneficial effects of DCLHb in reducing infarct size were not compromised by the co-administration of a NOS inhibitor. In contrast, co-administration of an NOS substrate significantly offset the benefits of hemodilution with DCLHb.

In patients surviving the initial hemorrhagic insult of a ruptured cerebral aneurysm, delayed cerebral ischemia

with infarction, due to vasospasm of cerebral arteries, is a major cause of death and disability (89). OxyHb, among other erythrocyte breakdown products, is thought to be a major factor in the pathogenesis of cerebral vasospasm after subarachnoid hemorrhage (90). Therefore, administration of a tHb might have a detrimental effect on cerebral perfusion after subarachnoid hemorrhage. Cole evaluated the effect of subarachnoid administration of DCLHb, blood, or an artificial cerebrospinal fluid on cerebral blood flow in a spontaneously hypertensive rat model (91). Although subarachnoid Hb statistically increased the area of hypoperfusion compared with artificial cerebrospinal fluid, the area of hypoperfusion was only about 20% of that observed after a similar volume of blood was given in the subarachnoid space. Significantly, despite the observation that DCLHb slightly increased the area of hypoperfusion, infarct size was lower in the presence of this tHb.

Taken together, all of these preclinical studies supported completion of a randomized, prospective trial of DCLHb administration to stroke patients (92). In this Phase II study, increasing doses of DCLHb (25, 50, and 100 mg/kg, $n = 8$, 8, and 11, respectively) or placebo (normal saline; $n = 26$) were infused intravenously every 6 h for 72 h to patients with an acute ischemic stroke, consistent with localization in the anterior cerebral circulation. Patients were selected who had suffered the present stroke symptoms for less than 18 h, in whom a brain-computed tomography scan was normal or compatible with a recent infarction, and who were likely to survive for at least 3 months. Blood pressure (MAP) and HR were measured every 15 min, and plasma concentrations of endothelin-1 (ET-1), catecholamines, renin, vasopressin, and atrial natriuretic peptide were measured before and 24 h and 77 h after the start of infusions. In addition, blood was sampled for routine laboratory evaluations of liver enzymes, blood urea nitrogen, serum creatinine, creatine phosphokinase, and a complete blood count. In the placebo group, MAP was 112 (109–115) mm Hg at baseline and decreased spontaneously with time, a common observation in stroke patients. This decrease in MAP was attenuated in patients treated with DCLHb, reaching statistical significance in the highest dose group. (Nonetheless, there was no need for antihypertensive treatment in comparison with the control group, nor were there any signs or symptoms of hypertensive encephalopathy or hemorrhage into the infarct.) In contrast to the marked fall in MAP, HR did not change in the placebo group during the 66 h after start of infusions, but it had decreased at both time points after infusion of the highest dose of DCLHb. The plasma ET-1 concentration decreased slightly in the placebo group, from a value near the high extreme of the normal range toward the

midpoint of that range after 24 h and 66 h, but increased dose-dependently in response to DCLHb infusion. With the highest dose of DCLHb, the plasma ET-1 concentration rose from the high normal range at baseline to 4- or 5-fold higher values after 24 h and 66 h ($P < 0.001$ at both intervals). The increases in the plasma ET-1 concentration and in MAP were correlated ($r = 0.30$, $P = 0.02$). Other vasoactive hormones were not affected by the DCLHb infusion, and their concentrations did not correlate with the observed increases in plasma ET-1 concentration (93). Side effects considered directly related to DCLHb included a transient yellow discoloration of the skin and sclerae (0/8, 1/8, and 11/11) and hemoglobinuria (2/8, 6/8, and 11/11). The hemoglobinuria was caused by excretion of DCLHb in the urine and was not associated with any impairment of renal function as assessed by serum creatinine. In a 3-month monitoring period that followed, 3/26 control patients died, all of whom were in the high-saline group and 7/27 DCLHb patients died (3/8, 1/8, and 3/11) ($P = 0.16$). Treatment with DCLHb did not have a favorable effect on the neurological outcome as assessed by the Rankin disability score. In contrast to the favorable effects associated with expression of Hbs pressor activity in the preclinical studies, the absence of a fall in blood pressure in the DCLHb group, while well tolerated, did not have a beneficial effect on survival or degree of disability. It was concluded that administration of DCLHb in this patient population resulted in significantly worse neurological outcomes and more deaths than conventional treatment.

Cardiac ischemia

PTCA is an established therapeutic procedure for the treatment of obstructive coronary artery disease. Balloon inflation during PTCA produces a transient interruption of coronary blood flow to the vascular bed distal to the inflation, giving rise to temporary regional myocardial ischemia and increased risk of ventricular arrhythmias. Perfusion of the distal bed with an oxygen-carrying solution during PTCA has been shown to have beneficial effects (94). However, the use of a perfluorocarbon emulsion approved in the United States for this indication, FluosolTM DA 20%, was relatively inconvenient and has had questionable results (95). (This product is no longer marketed.) Since a tHb transports oxygen in a similar way to whole blood and can be perfused through an angioplasty catheter during balloon occlusion, it was hypothesized that use of a tHb may increase myocardial oxygenation and reduce myocardial ischemia during PTCA. This hypothesis has been tested in a swine model, and it was found that perfusion with DCLHb during PTCA allowed the extension of balloon occlusion times to 4 min or longer

without a significant decrease in cardiac function (96). Although these preliminary findings are encouraging, no additional preclinical or clinical trials of a tHb have been reported for this indication.

Improvement of Oxygen Delivery in Sick Cell Anemia Patients

Sickle cell anemia is a genetic disorder characterized by chronic hemolysis and intermittent vaso-occlusive crises. An element of the pathophysiology of these vaso-occlusive episodes is tissue ischemia and/or infarction subsequent to an impairment in oxygen delivery. Recently, a Phase I/II clinical study was completed in which a single dose of 0.2, 0.4, or 0.6 g/kg of HBOC-201 was administered to adult patients with sickle cell disease (97). Normal saline solution was used as the control. The subjects were not in crisis at the time of the study. The parameters used to assess the safety of the hemoglobin included vital signs, clinical laboratory tests (complete blood counts, urinalysis, coagulation profile, serum electrolytes, and tests of renal and liver function), transcutaneous oximetry, and an adverse experience profile. In addition, each subject underwent an assessment of selected aspects of muscular function consisting of a hand-grip strength test and an aerobic capacity evaluation. The latter tests were performed at baseline (16 h prior to the administration of study treatment) and 4 h and 48 h after the initiation of HBOC-201 infusion.

The HBOC-201 infusions were well tolerated by the subjects, and no evidence of toxicity was noted. There was no appreciable change in the circulating hemoglobin level, the blood pressure, or any of the other hematological or clinical laboratory parameters. Hemoglobin was not detected in the urine, nor were signs of liver or kidney toxicity observed. The hand-grip testing showed no significant differences between the study treatment groups at any of the testing sessions. Although the exercise intensity for all of the patient groups during each of the aerobic exercise tests was not different, HR responses of the HBOC-201 patients differed significantly from those of the placebo patients at the various exercise levels. At +4 h, the HR of the subjects who had received HBOC-201 were significantly lower than the HR that these same subjects had exhibited during their baseline exercise period. At +48 h and in the saline group, these differences were not observed. Likewise, at +4 h there was a smaller rise in the lactate level of the HBOC-201 subjects as compared to the baseline period; this difference was not statistically significant, nor was it observed at +48 h or in the placebo group.

Thus, this study in sickle cell disease patients appeared to support the findings of a parallel study in normal human volunteers, where it was concluded that HBOC-201 apparently supported submaximal exercise capacity in a manner quite similar to autologous blood, but at lower pulse rate, CI, and lactate concentration (98). The results of both studies suggest that the provision of acellular Hb may be an efficient way to deliver oxygen to the tissues.

Resuscitation Following Pressure Contusions

The administration of small volumes of a therapeutic hemoglobin solution has also been proposed for the treatment of two types of lethal, pressure-related injuries. The first type of injury is a contusion or barotrauma-like injury to the lungs and gastrointestinal tract resulting from blast overpressure (the abrupt, rapid rise in atmospheric pressure resulting from explosive detonation) or nonpenetrating trauma (99). The second type of injury is severe head injury and associated hypotension. For example, pulmonary contusion occurs in almost 20% of nonpenetrating trauma admissions with multiple injuries (Injury Severity Score of >15); (Yale Trauma Registry), and is associated with a marked increase in the frequency of pneumonia, respiratory failure, adult respiratory distress syndrome, and death. In survivors, the probability of chronic, disabling respiratory problems is increased. Likewise, head injury is the leading cause of traumatic death in the United States; when associated with hypotension, the incidence of adverse outcome (severe disablement, vegetative quality of life, or death) is increased significantly. Injuries of these types are complicated by secondary damage, often at sites remote from the area of primary injury. Aggressive resuscitation to restore tissue oxygenation can prevent secondary insults and improve outcome. However, since these injuries are accompanied by edema, aggressive fluid resuscitation with large volumes of electrolyte solutions may be contraindicated. In contrast, low volume resuscitation with a hyperoncotic, oxygen-carrying hemoglobin solution has the potential to restore tissue perfusion and oxygenation and minimize water accumulation at the site of injury and the surrounding tissues.

Cohn et al. used a swine model to determine the impact of a vasoactive red cell substitute on respiratory derangements after traumatic lung injury (100). Young Yorkshire pigs ($n = 6/\text{group}$) were anesthetized and mechanically ventilated. Each animal then received pneumatic blasts to the right thoracic cage at baseline and was hemorrhaged a total of 30 ml/kg over 20 min prior to resuscitation with 0.9% saline (90 ml/kg) or diaspirin cross-linked hemoglobin (DCLHb; 15 ml/kg) from $t = 20$

to 40 min. The infusion of maintenance fluids (in the saline group and 4 ml/kg/ in the DCLHb group) was continued until the end of the 4-h observation period following the initial injury. Serial pulmonary and systemic hemodynamic measurements were used to monitor pulmonary and hemodynamic status, and total thoracic compliance assessment, spiral three-dimensional computed tomography scans, and lung weights ($n = 3/\text{group}$) were used to assess lesion size and lung water. MAP was restored in both groups but was significantly higher in the animals receiving the hemoglobin solution. Oxygenation worsened somewhat in both groups. Compliance worsened in both groups but was significantly worse at the end of the experiment in animals receiving DCLHb. The authors also found that resuscitation with DCLHb led to greater contusion lesion size. Thus, this therapeutic hemoglobin does not appear to have benefit in this model of barotrauma-like injury.

On the other hand, Shackford investigated small-volume resuscitation (4 ml/kg) using RL, hypertonic saline-dextran (HSD) and DCLHb in a porcine model of cryogenic brain injury and shock and found that both the HSD and the DCLHb had benefit in this model (101). In these experiments, swine were subjected to a cryogenic injury and a Wiggers-type hemorrhage and then resuscitated with a small-volume bolus of an asanguinous solution. The first regimen consisted of a bolus of RL followed by a constant infusion to return the MAP to baseline (RL/RL). The second regimen consisted of an initial bolus of 7.5% hypertonic saline in 6% dextran solution followed by a continuous infusion of RL to restore the MAP to baseline (HSD/RL). The third regimen consisted of a bolus of HSD followed by a constant infusion of hypertonic sodium lactate to restore the MAP to baseline (HSD/HSL). Shed blood was returned 1 h after the initiation of resuscitation in all three regimens. In a second experiment a test group received a bolus of DCLHb; no shed blood was returned. In summary, small-volume resuscitation with either hypertonic solutions or with hemoglobin solutions had favorable effects on the cerebral perfusion pressure with decreasing intracranial compliance.

The clinical management of brain injury includes the use of osmotic and other diuretics to attempt to control tissue edema and agents which modify the rheology of blood in order to better perfuse the brain and counter ischemia. Two recent reports summarize the effects of hemodilution with DCLHb or oncologically matched plasma protein solution following traumatic brain injury in rodents. Piper monitored intraventricular intracranial pressure (ICP) and CBF in the region of the sensorimotor cortex 4 h after a severe weight-drop injury to the brain

and found that DCLHb significantly reduced ICP from mean 13 ± 2 to 3 ± 1 mm Hg ($P < 0.001$) and increased CBF from 21 ± 2 to 29 ± 2 ml/100 g/min ($P = 0.032$). It was concluded that DCLHb improved coronary perfusion pressure without a reduction in CBF in this rodent model of posttraumatic brain swelling (102). Likewise, Muldoon examined coronal samples of the hippocampus for the presence of necrotic neurons following traumatic brain injury to anesthetized rats treated by hemodilution with DCLHb or oncologically matched human serum albumin (103). Whereas treatment with albumin showed a trend toward a reduction in the number of necrotic neurons in the hippocampus, treatment with DCLHb significantly reduced neuronal necrosis at this site, suggesting that hemodilution with the tHb decreases hippocampal neuronal ischemia when administered following traumatic brain injury.

These preclinical results suggest further investigation into the use of therapeutic hemoglobins after severe head trauma may be warranted.

SAFETY

With the infusion of an acellular tHb, the Hb concentration in the plasma rises from 1 to 3 mg/dl (normal values) to concentrations as high as several grams per deciliter. Concentrations such as these are sufficiently high (≥ 15 mg/kg) to overwhelm the ability of haptoglobin, the physiological hemoglobin scavenger, to bind and remove it from the circulation (14). In addition, some tHbs do not bind to haptoglobin, negating its value for Hb removal.

The protein is administered and circulates for varying lengths of time as oxyHb. However, with time, the ferrous iron contained in each heme ligand undergoes either auto- or chemically induced oxidation, yielding metHb (104, 105). The rate at which Hb oxidation occurs depends on many factors, including the structure of the Hb, the concentrations of natural or exogenous oxidizing agents and perhaps, the pathophysiological state of the patient (106). Oxidation of acellular Hb to metHb is a continuous process, in contrast to the condition within the red cell, where the metHb concentration is normally maintained at 2–3% of the total Hb by the methemoglobin reductase system (14). Therefore, the metHb content of an acellular Hb can rise to very high percentages of the total circulating Hb; the maximum plasma metHb concentration, however, is typically several hundred mg/dl.

Within the red cell, enzymatic systems reduce the metHb to Hb (14). In the plasma, however, the

concentrations of metHb-reducing agents are very low. The only effective *in vivo* reducing agent system for acellular metHb apparently is exported from the red cell; the ability of this unidentified agent to reduce metHb *in vitro* has been demonstrated in several laboratories (62, 63) but is difficult to quantify *in vivo*.

Finally, the possible presence of high concentrations of metHb in the plasma raises concerns about inappropriate release of heme and iron. Whereas normal plasma concentrations of heme are negligible, heme-protein interactions are weakened in metHb, as a result of which heme may be transferred to lipophilic surfaces, such as RBC or endothelial cell membranes. Heme-association at these sites has been reported to promote cell lysis, either as a direct effect or through synergistic effects with hydrogen peroxide (108). Similarly, scientists and clinicians have long recognized the ability of iron, both “free” and sequestered within enzymes, to catalyze oxidation reactions *in vitro* and *in vivo*. Thus, the safety of administration of large quantities of a redox-active Hb continues to be actively debated (109–112).

Given these possibilities (summarized in Fig. 2.), if a redox-active, acellular Hb was to exacerbate injury, it is reasonable to anticipate that cell and tissue exposure *in vivo* to large quantities of Hb would have both directly and indirectly observed consequences. For example, if generation of reactive oxygen species (e.g., superoxide radical anion, hydrogen peroxide, or peroxynitrite) were a consequence of Hb exposure, increased leukocyte adhesion, peripheral blood mononuclear cell activation, and changes in cell-wall integrity would typically be observed. Likewise, indirect effects of Hb-related injury would also be expected, such as increased sensitivity of protein-overloaded cells to ischemic damage (in the renal

tubular epithelium, for example, where uptake of acellular Hb is known to occur) or cell-surface obstruction caused by Hb binding or deposition (e.g., cast formation in the renal tubules, a frequent observation following infusion of native, unmodified Hbs).

Numerous concerns about the safety of hemoglobin preparations have been presented in the literature. Some of the historical safety concerns have been addressed and are no longer issues with respect to the hemoglobin formulations now in advanced clinical trials. For example, effects such as neutrophil and macrophage activation, the formation of microthrombi, and platelet aggregation appear to have been eliminated from these Hb formulations. However, new safety concerns, centering on effects that have been observed clinically, have been raised. Three principal concerns will be discussed here: 1) Hb's pressor activity, 2) the potential for acellular Hb to exacerbate injury, and 3) the potential for Hb to potentiate or exacerbate infection.

Hemoglobin's Pressor Activity

Following the infusion into mammals of most, if not all, tHb solutions, increases in mean arterial and pulmonary artery pressures and systemic and pulmonary vascular resistances are observed. The observations vary with the species and the preclinical or clinical model being studied. For the most part, the increases in MAP are rapid but apparently self-limiting (i.e., there is no continuous, dose-related escalation). Their duration apparently depends on the structure or some other property of the Hb infusate and the dose administered.

A growing body of evidence indicates that the interplay of multiple mechanisms contributes to Hb's pressor activity. Some of these mechanisms, namely, the blood pressure increases related to Hb's oncotic properties and viscosity, appear to be of lesser importance. For example, significant pressor activity is not observed following infusion of oncotically matched albumin solutions or molecular weight-paired dextran or hydroxyethylstarch solutions. Likewise, the vasoconstriction elicited by the Hb solutions appeared to override the vasodilation associated with decreases in viscosity due to hemodilution (113).

Both NO and endothelin-1 (ET-1), acting in concert with each other and in synergy with other vasoactive substances, are believed to mediate a broad spectrum of physiological actions, including homeostatic regulation of blood pressure, vascular tone, and blood flow to various tissues, as well as enzyme and fluid secretion in organs such as the kidney and pancreas (114–116). Since the Hb-related effects on blood pressure and hemodynamics appear to involve both of these mediators, two key

Fig. 2 Potential mechanisms for Hb-mediated injury.

questions have been raised. One, does the Hb-related increase in blood pressure, commonly viewed as a sign of sufficient resuscitation following hemorrhage, mask on-going, decreased organ perfusion and local ischemia in the microcirculation of key organs such as the heart, liver, kidney, or gut? In hypovolemic or ischemic states, tissue perfusion and oxygenation already may be compromised in these critical areas, and augmented vasoconstriction could exacerbate injury. Two, do the mechanisms underlying the pressor effect alter the functionality of other critical physiological systems, particularly those in the secretory organs (e.g., the kidney or pancreas)? Both questions remain at the forefront of clinical and regulatory concerns.

To address the first of these concerns, many preclinical studies on the effects of Hb administration in hypervolemia or resuscitation from hemorrhagic shock have been completed using a variety of techniques. For example, the effects of tHb on the perfusion of microcirculation have been assessed using hemodynamic measurements, acid-base status, radioactive microsphere measurements, blood flow measurement with ultrasonic flow probes, and intravital microscopy (39). Oxygenation of key tissues has been assessed via palladium porphyrin phosphorescence techniques, microplatinum electrodes placed in muscle tissue, oxygen-sensing electrodes, and measurement of whole body oxygen consumption. A spectrum of studies in a variety of animal models of hemorrhagic shock have demonstrated that resuscitation with a tHb typically restores MAP, base deficit, and subcutaneous and mucosal pO_2 to baseline levels (118–120). Studies of the microcirculation in organs susceptible to post-ischemic organ damage, such as the gut or pancreas, have shown a restoration of microcirculatory function by a tHb comparable to that achieved by blood transfusion (121, 122). Likewise, the administration of a tHb to septic animals has been shown to restore MAP and systemic vascular resistance and maintain blood flow to key organs (123). Taken together, the experimental data suggest that the pressor effect induced by a tHb may alter blood flow in the microcirculation and key organs in beneficial ways, although the redistribution of blood flow may vary from Hb to Hb (124, 125).

With respect to the second question, numerous recent reports suggest that the scavenging of NO by Hb or the increases in ET-1 may have both local and remote systemic effects. Thus, NO-scavenging by acellular Hb has been proposed as a cause of the frequent occurrence of gastrointestinal symptoms reported following the infusion of a genetically engineered, intramolecularly cross-linked Hb (126, 127) and o-Raff-Hb (56) in humans. Similarly, it has been proposed that the elevations in serum amylase

and lipase observed following infusion of many tHbs may also relate to an inhibition of NO-mediated activity or increased plasma ET-1 (128). For example, ET-1 is known to reduce pancreatic perfusion (129), and its Hb-augmented synthesis or release may adversely influence microcirculatory oxygenation.

Although the renal safety profile of the current generation of tHbs appears to be satisfactory, Hb modification greatly reduces, but does not eliminate, Hb uptake and filtration in the kidney. Hypothetically, therefore, the presence of high concentrations of acellular Hb in the tubular cells kidney could interfere with the processing of other proteins by this organ. Interestingly, Gburek et al. have recently identified Hb binding sites in the distal tubule of the rat kidney that recognized a motif common to rat, human, and swine hemoglobins (130). If similar binding sites are identified in human Hb-processing organs, it is reasonable to consider that the slow pinocytotic uptake of bound Hb could interfere with the binding of other proteins and peptides, an interference that would effectively elevate plasma concentrations of these moieties.

Preliminary data concerning clinical trials in which a tHb has been infused in resuscitation from hemorrhagic shock or as a substitute for blood have shown widely disparate findings. The available data are likely too sparse to draw conclusions as to whether the pressor activity of a tHb or its absence is a meaningful factor in the therapeutic utility of a tHb.

The overproduction of NO in septic shock has made this molecule a major target for therapeutic intervention in endotoxemia (131, 132). Since nitric oxide synthase (NOS) inhibitors such as arginine derivatives (e.g., L-NMMA, L-NAME, and NNLA) or methylene blue appear to improve blood pressure and vascular function, the potential usefulness of these agents for treatment of septic shock has been advocated. However, clinical studies using these inhibitors, although limited in number, indicate that these unselective NOS inhibitors may not improve survival, even though they increase MAP and vascular resistance and partially restore vascular reactivity to noradrenaline (133). The NO-scavenging actions of Hb have prompted both preclinical and clinical studies of its therapeutic benefit in treatment of septic shock. For example, a recent study using a rodent model of endotoxemia compared the effects on hemodynamics and renal function of polymerized bovine Hb, HBOC-201, with those of NOS inhibitors (67). The results clearly indicated that treatment with HBOC-201, but not with unselective NOS inhibitors, could improve both renal and cardiovascular function in rats suffering from septic shock.

Clinical trial data for this indication also are sparse. An observational study of the hemodynamic effects of DCLHb in 14 critically ill patients with septicemic shock or systemic inflammatory response syndrome suggested a beneficial effect (71). Likewise, patient stabilization and a decrease in the requirement for vasopressor therapy has been observed following the administration of PHP-Hb in volume-refractory, vasopressor-dependent shock patients (70).

The Potential for Acellular Hb to Exacerbate Injury

Whereas the adverse findings described above have sometimes been reported following completion of in vitro experiments, in general, they have not been demonstrated in preclinical and clinical studies of tHbs. Thus, preclinical studies in a sizeable number of animal species have generally shown no signs of inappropriately rapid Hb degradation (i.e., unusually rapid oxidation to metHb or unanticipated heme loss), no changes in the concentration of non-transferrin bound iron in the serum, and an absence of toxicities related to hemin or bilirubin-induced red cell hemolysis following volume-load, or partial or complete exchange of the test animal's blood for a tHb (134). Similarly, intravital microscopic studies of the microcirculation following hemorrhagic shock and resuscitation with a tHb solution have generally revealed a restoration of microcirculatory function not realized following resuscitation with crystalloid or colloid solutions (135). Moreover, resuscitation with a tHb solution has tended to restore functional capillary density to prehemorrhage conditions and is generally complemented by an absence of signs of damage to the endothelium, such as increased leukocyte adhesion or increased endothelial cell-wall permeability to dye-labeled macromolecules. Although some groups have observed an elevation in the concentration of thiobarbituric acid-reactive materials in the tissue or conjugated diene release following Hb exposure, histopathologic changes (edema, necrosis, cell infiltration, and hemorrhage) or significant reductions in organ function were generally absent (136). Moreover, surrogate markers of effective resuscitation, such as a restoration of physiological, acid-base balance or intestinal mucosal pH_i, suggest that microcirculatory function has been restored.

In the various trials conducted to date, hundreds of patients have received low-to-moderate doses of a tHb solution in clinical tests. A limited number of patients have received larger doses of 100–500 g of a tHb. For the most part, the infusions have been well tolerated. However,

several observations have been made relatively consistently and will be discussed below.

Pseudojaundice

A tHb cleared from the systemic circulation will undergo catabolism to bilirubin in several organs and tissues, including the kidney, liver, and spleen. Following the administration of a tHb to animals, increases in liver weight at necropsy and microscopic observations of pigmented Kupffer cells are common observations. Liver sections stain with Prussian blue, suggesting that an iron-containing pigment is present within hepatocytes and Kupffer cells. The absence of elevations in ALT indicates these changes are not associated with liver hepatotoxicity. The pigmentation decreases markedly during the recovery period. All of these observations point to increased acellular Hb catabolism by this organ. Consistent with this catabolism, during preclinical studies in animal models, serum bilirubin concentrations increased following the infusion of a tHb and gradually returned to normal values during the recovery period.

This pseudo-jaundice has also been observed clinically. In a study in critically ill patients, the most common observation following the administration of DCLHb was the observation of a yellowing of the patient's skin, which was either of new appearance or was an increase in the intensity of a pre-existing color change (71). The effect was documented in 6 of the 14 patients in the study; 3 of the affected patients had received a total of 20 g of DCLHb (200 ml), and 3 a total of 50 g (500 ml). Uniformly, the effect was transient: color peaked at 24 h post-infusion and decreased to pre-infusion levels within 5 days. The pseudo-jaundice was associated with an increase in bilirubin but with no significant change in any other liver function test. A similar incidence of transient pseudo-jaundice was also reported for 39 of 104 patients in the cardiac surgery trial of DCLHb (54). These patients generally received 25 to 75 g (250–750 ml) of DCLHb. No signs indicating liver dysfunction were observed. A review of the data indicates that it is likely an expected result of the intracellular metabolism of the plasma Hb.

Likewise, in the first 3 days following the infusion of PolySFH-P, the total bilirubin concentration increased to 2.4 ± 1.7 g/dl and then gradually declined (53). Although not cited as an adverse event in the report, the consequences of bilirubin concentrations as high as these are controversial. In an otherwise healthy infant, for example, these high bilirubin concentrations would cause concern about bilirubin neurotoxicity (137). However, under certain circumstances, it has been hypothesized that bilirubin may act as a natural antioxidant (138), and perhaps, that is the case here.

Although preliminary data from clinical trials of Hb-PHP or HBOC-201 are not available, it is reasonable to anticipate that as these tHbs are cleared from the circulation and metabolized, total bilirubin in the plasma will increase and then decline.

Enzyme and autocoid peptide elevation following hemoglobin infusion

A reversible elevation in the concentrations of several serum enzymes or autocoid peptides has been seen in preclinical studies following single and repeated dose infusions of some tHbs. For example, in various studies, the infusion of a single dose of DCLHb (100–4000 mg/kg) in rats, dogs, and monkeys caused mild-to-moderate increases in the concentrations of AST and sorbitol dehydrogenase (SDH) (139). No histopathological changes were associated with these increases, and the enzyme concentrations returned to baseline values during the recovery period. Since similar AST elevations were seen following infusion of albumin solution, it was hypothesized that the increases might be related to the volume and protein load that was administered.

Likewise, following the repeated infusion of doses of 1000–2000 mg/kg DCLHb daily for 7 days or of 400 mg/kg every 6 h for 3 days, the concentrations of AST, lactate dehydrogenase (LDH) and creatine kinase (CK) were elevated in monkeys (139). Isoenzyme profiles for CK and LDH revealed predominant increases in the MM form of CK and the LD-5 form of LDH. The MM-CK originates predominantly from skeletal muscle and may also derive from the myocardium; however, the MB isoenzyme, which emanates only from myocardium, was not elevated. The elevation of LD-5 was also consistent with a skeletal muscle source.

Similarly, transient elevations of AST, ALT, γ -glutamyl transferase, and LDH were observed in dogs following the administration of 0.6 g/kg doses of o-Raff-Hb (56). The changes were related to liver catabolism of this acellular Hb.

Hemorrhage leads to an increase in the plasma ET-1 in rats and dogs and may be a part of a natural compensatory response (140, 141). The higher concentrations likely result from increases in the synthesis or release of ET-1 as a consequence of hemodynamic changes (142), because of the activation of stress hormones or the coagulation cascade (136), or as a result of a decreased clearance in the liver, kidneys, and lungs, organs where ET-1 is metabolized (117). In vivo studies have recently confirmed a significant role for the autocoid peptide ET-1 in the cardiovascular pressor effects observed following the administration of DCLHb (143). An increase in the plasma ET-1 concentration has been correlated with the DCLHb

pressor activity in rats and swine and with constriction of isolated pig pulmonary vessels (144–147). However, maximizing the predictive value of this information has been difficult, because the ET-receptor types and their density show considerable variability, both within tissues and organ systems and from species to species (142). Moreover, no information is available about the relationship between Hb structure or properties and increases in ET-1 concentrations.

Transient elevations of these same serum enzymes have been observed in clinical trials of the various tHbs. For example, at the 0.6 g/kg body weight dose of o-Raff-Hb, changes in total bilirubin, AST, ALT, γ -glutamyl transferase, and LDH levels were noted (148). The changes had no clinical significance and were ascribed to Hb catabolism by the liver. In addition, transient increases in serum amylase and lipase, markers of pancreatic function, were observed at the 24 h time point in patients receiving this dose. The magnitude and time course of these latter changes were not consistent with the pattern observed in acute pancreatitis and were not considered to be clinically significant.

Transient rises in serum AST also were observed in clinical trials of DCLHb in surgical and critically ill populations (54). Serum amylase elevations were observed in clinical studies of DCLHb after single or cumulative doses of 20 g or more of DCLHb. These elevations are typically 2–3 times the upper limits of normal serum enzyme concentrations. The low incidence of acute pancreatitis observed in these trials was at the expected level for these patient populations (148).

Finally, transient rises in serum AST and amylase were observed in a study of the clinical utility of PolySFH-P in acute trauma and urgent surgery patients (53). In the 24 h following infusion of this tHb, the concentrations of AST nearly doubled but declined toward pre-infusion levels thereafter. Similarly, for 3 days following infusion of PolySFH-P, the concentration was about double the pre-infusion level. The changes were not considered to be clinically significant.

Clinical trials of DCLHb have revealed that ET-1 plays a role in the hemodynamic effects induced by at least one tHb (92). Peripheral circulating levels of ET-1 in human plasma (1.6–4.9 pg/ml) are normally far below the concentrations associated with pathological conditions (142). However, infusion of repeated, 100 mg/kg doses of DCLHb was associated with a 4- to 5-fold increase in the plasma ET-1 concentration (92) to values equal to or higher than the ET-1 concentrations determined following an acute myocardial infarction, cardiogenic shock, or heart failure (149, 150, 151). Although an increase in the ET-1 concentration of this magnitude may be a response

peculiar to DCLHb, a clinical concern remains that other tHbs may also induce ET-1 release, albeit in lower quantities. In vivo, even low levels of the peptide may amplify the constrictor effect of other circulating hormones or autocoids such as NO (152).

The Potential for Hemoglobin to Potentiate or Exacerbate Infection

A major anticipated use of acellular Hb would be for the emergency treatment of patients with traumatic hemorrhagic shock. The probability of associated bacterial infections in this patient population is high. Thus, the potential for hemoglobin to potentiate or exacerbate bacterial infection has been discussed widely.

A lethal synergy of bacteria and some component of blood was first described in 1890. Initially Hb was identified as the causative agent in blood (153), but subsequent studies implicated hemin and iron as the likely factors in promoting mortality (154, 155). An acellular (met)Hb is potentially a source of both.

Moreover, it has been hypothesized that exposure to an acellular Hb may injure the epithelium of the gastrointestinal tract (156). Under normal conditions, this tissue acts as a highly selective barrier, which permits the absorption of nutrients but restricts the passage of microbes and potentially toxic macromolecules from within the lumen into the systemic compartment. Derangements in the barrier function of the gut have been implicated as being important in the increases in intestinal permeability in patients with sepsis or in burn victims (157), in patients with multiple trauma (158), and in patients undergoing cardiopulmonary bypass or major surgery (159), and in the pathogenesis of multiple organ system dysfunction in critically ill patients (160). In addition, the development of GI mucosal acidosis, a predictor of multiple organ system dysfunction and/or mortality in critically ill patients (161, 162), is strongly associated with the development of increased mucosal permeability (163). Compromised morphology of the intestinal barrier is a consistent finding in hemorrhage without resuscitation (164). However, the administration of a tHb frequently restores the pH_i in the intestine (165–168). Moreover, following the use of a representative tHb, DCLHb, histopathologic examination of intestinal tissue samples indicated cell wall integrity was maintained (169). In addition, tissue culture supported the conclusion that bacterial translocation was attenuated.

Whether or not Hb accentuates lethal effects of endotoxin is also not resolved. When inoculation with living *E. coli* or endotoxin has been used to induce sepsis

in mice, some Hb preparations have been found to demonstrate deleterious effects (170–172). In contrast, other studies using better characterized, modified Hb solutions have failed to confirm these findings, both in mice and in other animal models (172, 173).

For example, the hypothesis that DCLHb would improve blood pressure, organ perfusion, and mortality was tested in a rodent model of sepsis (169). Administration of this tHb to moribund, septic rats immediately reversed the decreased MAP, increased systemic vascular resistance (SVR) and by 24 h, significantly elevated perfusion to vital areas (intestines, heart, and brain) as compared to albumin-treated animals. In addition, areas that did not display an increase in perfusion also did not demonstrate any deficits, suggesting that they were being adequately perfused.

Similar observations have been made following the infusion of bolus doses of 50, 100, or 200 mg/kg of Hb-PHP in septic sheep (175). All three doses of Hb reversed the hyperdynamic circulation that had developed during sepsis by increasing MAP and SVR while decreasing CI. Although pulmonary arterial pressure increased after Hb infusion, it neither adversely affected arterial oxygen saturation nor resulted in the development of pulmonary edema. Moreover, there were no significant increases of conjugated dienes in the lung tissue, suggesting that increased free radical production is unlikely after the infusion of low doses of this tHb. Following administration of the 100 mg/kg dose, the increase in serum iron concentrations, while significant, never exceeded the iron-binding capacity, suggesting that no free iron was available to increase bacterial growth. No differences were seen between the Hb and control group in pulmonary bacterial clearance (the lung is the major organ of the RES in sheep) or in white blood cell counts and white blood cell differentiation, suggesting an absence of Hb-related interference with the activity of the reticuloendothelial system in this model. None of the animals treated with Hb died after treatment.

Although preliminary, the data from clinical trials of the various tHbs parallel the observations in the preclinical studies described above. For example, DCLHb was administered to critically ill patients with septicemic shock or systemic inflammatory response syndrome in two studies. In the first of these studies, serum iron concentrations were increased following administration of the tHb; however, no obvious toxicity or development of overwhelming sepsis occurred (71). On the contrary, measurable patient benefit appeared to derive from its administration. Likewise, in the second study, where DCLHb was used in the treatment of acute anemia in 23 critically ill, predominantly septic patients, oxygen

delivery, oxygen consumption, as well as overall organ function and metabolic status were maintained or improved during the 24 h following treatment (176).

Moreover, tHbs have been administered to patient populations that included sizeable fractions of elderly and anemic patients or patients having co-morbidity. Enhanced susceptibility to infection or its exacerbation following the administration of a tHb to these patients has not been reported. Taken together, the preliminary data from clinical trials suggest that a tHb may provide significant benefit in a variety of clinical indications where sepsis may develop or is present.

STATUS OF CLINICAL TRIALS

Given the hurdles and the costs associated with the development of a clinical product that is a new biologic, it is remarkable that at least five companies continue to be engaged in clinical trials of hemoglobin-based oxygen carriers (Table 2). Most of the companies are developing modified hemoglobins derived from natural sources (human or bovine red cells), but at least one firm is using a biotechnological approach. Each of the hemoglobins under study is unique but has properties that are common to hemoglobin (e.g., its oxygen-transport capability and color) and properties that are unique to the particular therapeutic hemoglobin (e.g., its composition and formulation).

When this review was written, a spectrum of clinical trials were being completed at various locations around the world. Many of the trials were safety studies and dose-escalation studies that are best described as Phase I and II clinical studies. However, a few trials were definitive Phase III efficacy studies that had a reasonable probability of culminating in regulatory filings. In these various trials, hundreds of patients have received low doses of hemoglobin solutions in clinical tests, and a more limited number of patients have received larger doses of 100–300 g of therapeutic hemoglobin (as much as 6 units of 10 g/dl hemoglobin solution). Lastly, development of two tHbs, DCLHb and rHb 1.1, had been discontinued following clinical trials that failed to demonstrate significant benefit. As of this writing, none of the current generation of therapeutic hemoglobins has been approved by a regulatory body for clinical use.

SUMMARY OF THE FIELD

Surprisingly, development of a therapeutic hemoglobin solution from one of the most familiar and best-

characterized proteins, hemoglobin, has been considerably slower than had been predicted or anticipated. Progress, although considerable, has been influenced by two major factors. One, clinical understanding of the maintenance of general and local circulatory homeostasis and the effects of oxygen deprivation is expanding and changing rapidly. Two, superimposed on this backdrop of expansion and change is the recognition that the biological and physiological consequences of the infusion of acellular hemoglobin solutions are incompletely understood. Each new report on clinical trials of the various tHbs makes it clear that effective therapeutic use of the current generation of hemoglobins will require a determination of the appropriate balance between benefits and risks, coupled with a careful match of the beneficial properties of a tHb to the clinical indication(s) to which it is best suited. The goal of the trials, however, remains constant. As Sloan et al. stated, the clinical objective is “a reflection of the earnest desire of the investigators to increase the survival chances of patients for whom standard therapy appeared to offer little hope” (94).

CAPSULES, HARD

Brian E. Jones

Shionogi Qualicaps, Alcobendas, Spain

INTRODUCTION

Hard or two-piece capsules have been produced since the 1840s (1). They were initially proposed for filling with oils and later were used for powders and other dry forms. The first patent was issued in France; however, the first industrial-scale manufacture took place in the United States in the 1870s. By the turn of the 20th century, millions of capsules per year were being filled in U.S. pharmacies because they met the need for an easily manufactured unit dosage form. Even though the use of capsules spread to other countries, they were considered an American specialty, and the manufacture of capsules did not spread to Europe and the rest of the world until the 1950s. The use of hard capsules increased greatly at this time because of the types of medicine such as antibiotics and antidepressants that were in vogue. This increase stimulated the production of fully automatic filling machines and self-locking capsules to meet the demands for high-speed industrial production. Hard capsules are welcomed by consumers because of their elegant appearance and shape, which is easy to swallow. The majority of capsule fills are dry powder blends, which are typically simple mixtures. The processing and filling of materials involve minimum stress and are the reasons why products are presented in this form. The formulator is able to prepare products that have the desired release characteristics, rapid, controlled, or modified, because of the limited number of factors involved. Hard capsules can be filled with formulations that have a wide range of physical properties from dry solids to nonaqueous solutions, thus enabling the formulator to use many different types of excipients to achieve the desired effect. Capsule products can be formulated to release their active ingredients at many sites along the gastrointestinal tract and to deliver them to the lungs.

RAW MATERIALS

Gelatin and Alternative Materials

Gelatin is a material derived from collagen, a natural protein, which is a fibrous material that occurs in the skin,

bones, and connective tissues of animals (2). It is insoluble in water and is solubilized by hydrolysis. The raw materials used for its manufacture are obtained primarily from bovine bones or porcine skins. The reaction can be carried out at an acid pH level, yielding a type A gelatin (which is primarily produced from skins) and at a basic pH level giving a type B gelatin (which is primarily produced from bovine bones). Gelatin is a heterogeneous product that is a mixture of molecular species, α -, β -, and γ -peptides. The proportions and molecular weights are dependent on the nature of the chemical process. Gelatin was the first material used for the manufacture of capsules because of its unique properties. It is ideal because it is edible, soluble at body temperature, forms strong thin films, and undergoes a gelation process at temperatures just above ambient (1). It has a few technical drawbacks. It is of animal origin, and thus there are certain religious or dietary restrictions on its use. During the 1990s, there had been concerns over the use of bovine materials because of Bovine Spongiform Encephalopathy, which originated in the United Kingdom. The situation in Europe was brought under control by the European Commission (EC), which brought into effect rules that reduced risks to a minimum (3). The parts of the animal that theoretically could be the most infectious, such as the brain, are removed at slaughter and excluded from further processing. All the animals, from which bones are used in gelatin manufacture in Europe, are subjected to pre- and postmortem veterinary inspections. The alkaline hydrolysis process was made the method of choice for bones by the EC because of the pH levels and temperatures used in the process. There are a limited number of producers of pharmaceutical-grade gelatin worldwide thus enabling the problem to be addressed efficiently.

Hard capsules have traditionally been made from gelatin using a dipping process. Gelatin is very well-suited to this because it is an excellent film former and changes in state from liquid to solid at temperatures just above ambient (2). The film produced is homogenous and very robust, and gelatin capsules can readily withstand the mechanical stresses of the filling and packaging operations. The primary drawback in the use of gelatin is that it contains water, which acts as a plasticizer to the film. Thus, if they are not stored properly, their properties

will change. When water is lost from the shells, they become brittle, and thus they are not suitable for hygroscopic materials. Moisture-labile substances cannot be filled into them. For certain markets, there are consumer requirements for a capsule of vegetable origin. Since the last century, people have been searching for gelatin alternatives. The primary problem to be overcome has been the need to obtain a system that gels in a manner similar to that of gelatin so that the same manufacturing process and machines can be used. In the 1950s, capsules of methylcellulose were produced; however, their use was soon discontinued because of poor *in vivo* solubility (1). More recently, hard capsules have been produced from hydroxypropyl methylcellulose (HPMC), either by using a modified production process with heated mold pins (4a, 4b, 4c) or by the use of additives to make a true gelling system (5a, 5b, 5c, 5d). Hard capsules made from HPMC have similar but different properties from gelatin capsules. Their primary advantage is that their moisture content is much lower, and even if this is removed, they retain their mechanical strength (6).

CAPSULE MANUFACTURE

Gelatin capsules are manufactured using a dipping process, which was first proposed by M. Lehuby in 1846 (1). The same process is in use today, but it has been improved and automated. It requires a large investment in machinery and a plant, which need to be operated on a continuous basis to make the process economic. This has resulted in capsules being made by only a limited number of companies worldwide.

The process starts by the preparation of a concentrated solution of gelatin in hot demineralized water. This solution is subjected to a low pressure to remove entrapped air bubbles. Small aliquots (20–30 L) of this solution are taken. To this colorants, either solutions of soluble dyes or suspensions of pigments, process aids such as sodium lauryl sulfate solution, and water to adjust the viscosity are added. The final solution has a concentration of 25–30 wt% of gelatin. This solution is then delivered to the capsule-manufacturing machine.

The manufacturing machines are housed in rooms supplied with filtered air, conditioned to 40–45% relative humidity (RH) and 22–25°C. The most commonly used machines are approximately 12 m long and 3 m high and are divided down the midline into two parts that are mirror images of each other (Fig. 1). The machines are divided lengthways into two levels, an top and a bottom. The caps are made on the left side and the bodies on the

right side of the machine. The gelatin solutions are kept in temperature-controlled, jacketed hoppers (Fig. 1A). From there, they are fed to the capsule-forming container, variously known as a dip pan or dip pot (Fig. 1B). This is a stainless steel jacketed vessel that is oblong with a box in the center. The gelatin solution is pumped into the box and overflows the edge, thus maintaining a constant height. The stainless steel mold pins are mounted in a row of 30 on mild steel bars. Sets of bars are held in a device operated by a cam, which raises and lowers them. The mold pins, which are at 22°C, are lowered into the gelatin solution, which is at 50–55°C. The gelatin immediately gels on the mold. The molds are slowly raised, and, as they do, the excess gelatin runs off (Fig. 2). The quantity picked up by the mold is proportional to the viscosity. The higher the viscosity of the gelatin solution, the more gelatin is picked up. Thus, the viscosity of the solution is used to control the thickness of the gelatin film. As the mold breaks the surface, a blob of gelatin forms on the end of the mold. The sets of bars are transferred from the bottom to the top level of the machine and, as they do so, the bars are rotated to spread the film evenly over the end of the mold pin. The gelatin film is completely set by the time the molds reach the top level of the machine. Sets of bars are grouped together and mechanically transferred through a series of drying kilns (Fig. 1C). In these, air at controlled temperature and humidity is blown over them. When the bars reach the end of the machine, they are transferred to the bottom level and pushed back toward the front of the machine. When the bars emerge from the drying kilns, the moisture content of the gelatin films has been reduced from 70% at dipping to approximately 16 wt%. The molds, which had been warmed at the start of the drying process, have returned to ambient machine room temperature.

The dried gelatin films are removed from the mold pins and cut to the correct lengths, and the cap and body pieces are joined together. This is done in the automatic section of the machine (Fig. 1D). Pairs of bars, one with bodies and one with caps, are passed into the central section. Metal jaws pull the films off the mold pins into collets, which grip them. The collets rotate against a knife, and the gelatin film is cut. The excess is sucked away and recycled. The two pieces are transferred to a central joining block and are closed to a set length, called the unclosed joined length. The capsules are not fully closed because the filling machines would have difficulty separating them. They are closed so that the “prelock” indentations on the cap are engaged by the body, which provides sufficient holding strength so that they will not separate in handling.

The manufacture of HPMC capsules uses a similar process, and there are two different approaches. The viscosity of HPMC solutions increases with increasing

Fig. 1 A capsule manufacturing machine: A) Gelatin solution storage tank; B) dip pan; C) drying kilns; D) automatic section. (From Refs. 5a, 5b, 5c, 5d.)

temperatures. Thus, if hot mold pins at $>60^{\circ}\text{C}$ are lowered into HPMC solutions at $20\text{--}25^{\circ}\text{C}$ material will gel on the molds. The manufacturing machines have to be modified to carry out this process (4a, 4b, 4c). The mold pins are also heated post dipping to hold the material in place before drying. Capsules made in this manner have a wall thickness twice that of standard gelatin capsules to give them sufficient mechanical strength for handling. In the other process using a gelling system, an HPMC solution is prepared that contains carrageenan USNF as a gelation aid and potassium chloride as a gelation promoter (5a, 5b, 5c, 5d). Capsules are manufactured in the same manner and to the same dimensions as gelatin capsules. The only difference in the process is that the rate of output is slower because the rate of gelation is slower than that of gelatin.

STANDARDS FOR EMPTY CAPSULES

Two sets of standards are set for empty capsules: analytical and functional (6). Capsules, like all other pharmaceutical preparations, must comply with good manufacturing practice (GMP) norms and must be made of materials that comply with pharmacopeial chemical and

microbiological standards. However, these tests do not indicate whether a capsule will run well on a filling machine. A series of functional tests are applied by the manufacturers. The critical dimensions of a capsule (the lengths and diameters of the caps and bodies) are checked. It is a continuous production process, and there will be a very small proportion of visually defective capsules. Standard statistical sampling methods are used to estimate quality from samples. The manufacturers and users agree on acceptable quality levels (AQL). The faults are divided into categories depending on the likely impact on capsule performance or the filling process. A different AQL is assigned to each category of fault.

STORAGE OF EMPTY CAPSULES

Empty gelatin capsules are designed to have a moisture content between 13 and 16%. The water acts as a plasticizer and is essential to maintain the flexibility and strength of the film. If falls below the limit, the capsules will become brittle; if its rises above the limit, they will soften. Empty HPMC capsules have a moisture content of 3–7%. These capsules can be dried to less than 1% moisture without losing their mechanical strength and

Fig. 2 Dip pan, capsule shell formation: (From Refs. 5a, 5b, 5c, 5d.)

becoming brittle (7). The water in hard capsules is tightly bound into the polymer structure and is insufficient for active bacterial growth (2).

The water content influences capsule dimensions as well. The dimensions vary slightly as moisture is lost or gained. As a general rule, the dimensions of gelatin capsules change by 0.5% for every 1% change in moisture in the range of 13.0–16.0% (1). HPMC capsules contain less water than do gelatin capsules, and the change in dimensions with moisture content is less. Thus, higher-speed filling machines must be operated in air-conditioned areas to achieve maximum performance. The moisture content of capsules depends on the conditions to which they are exposed (8, 9). Water will be lost or gained, and the absorption/desorption isotherm follows a marked hysteresis. In practice, this means that if capsules lose excessive amounts of water, they will not fully rehydrate when exposed to standard conditions, RH levels between 35 and 50%.

CAPSULE FILLING

The hard two-piece capsule can be filled with materials that have a wide range of physical properties. The types of formulations that have been filled into capsules are shown

in Table 1. This is possible because of the manner in which filling machines handle empty capsules. First, capsules are orientated so that they are all pointing in the same direction, with the body downward. The capsules are transferred into pairs of bushes: the opening in the base of the top bush only allows the passage of the body, thus trapping the cap. The body is separated from the cap by means of suction. The open end of the body is then presented to a dosing mechanism and material transferred into it. The cap is then replaced on the body and the capsule closed to the correct closed joined length. This is an important dimension because it ensures that the self-locking mechanism, a series of indentations on the cap and body, is engaged correctly. This allows filled capsules to be transported and packaged on automatic equipment without separating.

Filling machines are differentiated by the means by which they measure the dose of material. They are available with a range of outputs, from bench scale to high-output industrial scale and from manual to fully automatic.

Powder Filling

The majority of formulations that are filled into capsules are dry powder mixtures. The methods of measuring the

Table 1 Formulation types for filling into hard capsules

Dry solids	Semisolids	Liquids
Powders	Thixotropic mixtures	Oily liquids
Granules	Thermosoftening mixtures	Nonaqueous solutions and suspensions
Pellets	Pastes	
Tablets		
Capsules		

dose can be divided into two groups: dependent and independent. The dependent machines use the capsule body directly to measure the dose of powder, whereas the independent machines use a separate device. The literature available on the mechanics of capsule-filling is limited compared with that available for tableting. Part of the reason for this is that tablets, unlike capsules, are used in a wide range of industries outside the healthcare sector, and thus there have been many more workers in the field.

The first industrial filling machines were of the dependent type. Powder is transferred from a hopper directly to the capsule body. The flow of the powder is aided either by a revolving auger or by a vibrating plate. The powder mass inside these capsules is a loose fill. The fill weights achievable on these machines is often higher than that obtained on automatic independent-type machines because the body is overfilled, and thus the total internal volume of the capsule shell is used (10). The first successful industrial filling machine was the ubiquitous machine designed by the doyen of pharmaceutical engineering, Arthur Colton, and the most popular version was the Model No. 8. This is a semiautomatic auger-filling machine (Fig. 3). The empty capsules are fed, aided by suction, into a pair of doughnut-shaped plates, which separate them. The plate containing the bodies is transferred manually to a turntable, and the powder hopper is pulled over the top of it. Powder is forced by the auger into the bodies as their plate revolves under the hopper. The fill weight is controlled by the speeds of rotation of the turntable and the auger. The only way to achieve good uniformity of fill weight on these machines is to completely fill the bodies. Partial filling is not an option. More recently, modifications have been made to the design to bring them in line with GMP requirements. The first was the Quali-fillTM Model 8S developed by Eli Lilly & Co. in the 1980s. Since then, additional improvements have been made: the Quali-fill Model 10 from Schaefer Technologies, Inc. and the Ultra 8 II[®] from Capsugel. A fully automatic rotary auger-filling machine has been developed by Shionogi Qualicaps, the LIQFIL^{super} JCF40/80TM. This machine has a three-roller system for capsule orientation

and continuous feeding to a revolving disk assembly where the capsules are separated, filled, and rejoined. Other automatic dependent filling machines use vibration to aid powder flow into the bodies. The first such machine, the Osaka OCF 120, used a vibrating plate in the powder hopper. The bodies in their holders passed under the hopper. The cavities with the bodies were overfilled and raised up against a metal plate to push the excess inside powder inside. This system works well with dense, free-flowing material. Shionogi Qualicaps have made a modification to this method, the LIQFIL^{super} 40 and 80TM, which uses spring-loaded fingers to compress the powder into the capsule body after it has been filled using a vibrating plate system.

Most automatic machines used in industry are of the independent type and compress a measured amount of powder to form a plug. There are two types of mechanisms: the dosing tube (or dosator) and the dosing disk and tamping finger.

The dosing tube is the most widely used, and it originated in Italy. Current manufacturers are IMA (Zanazi & Farmatic) (IMA North America, Inc.), MG2 (MG America, Inc.), Macophar (Romaco, Inc.), and Bonapace. The plug is formed inside a tube with a moveable piston that controls the dosing volume and applies a force to form the plug (Fig. 4). The lower-output machines have an intermittent motion, whereas the higher-output machines are rotary. The intermittent machines

Fig. 3 Schematic diagram of auger filling system (Model No. 8): A) Auger; B) powder hopper; C) stirrer arm; D) pressure relief hole; E) capsule carrying rings; F) body ring holder.

tend to apply greater stresses to the powder than does the rotary machines because there is less time to form the plug, and thus formulations tend to require a higher level of lubricant. These machines are very versatile because the fill weight can be varied over a wide range by a simple adjustment to the position of the piston. The rotary machines can be linked to weighing devices and have automatic weight-control adjustment, which allows them to operate unattended.

The dosing disk and tamping finger machines form a plug in a similar but different manner. They are produced

by a number of companies: Bosch (T.L. Systems Corp.), A.W. Bohanan Co., and Index Manufacturing Co., Inc. The dosing disk, which forms the base of the powder hopper, has up to six sets of machined holes (Fig. 5). In a holder, above the powder hopper, there are sets of stainless steel tamping fingers corresponding to the holes in the disk. These machines have an intermittent motion. After the machine has indexed, and the turret is stationary, the tamping fingers are lowered into the powder bed. The fingers are set to different levels, and they penetrate into the plate and consolidate the powder

Fig. 4 Diagram of a dosator or dosing tube system (Zanasi RM63): A) Compression force platen; B) piston; C) dosing tube; D) powder hopper; E) plug ejection platen; F) capsule body in bush; G) powder plug.

in the cavities into plugs. Thus, the plug is formed in a series of tamps and not in a single motion as on the dosator machines. The dosing disks are produced in a range of thicknesses for each size of capsule. Thus, the selection of the correct thickness of disk is important because if the fill weight cannot be achieved, the machine has to be dismantled to change it. The selection of the optimum disk thickness for a formulation can be made either pragmatically using a simple test rig (11) or systematically by using an Instron tester to determine plug density and strength of a formulation at known compression forces (12).

Bench-scale filling machines

There are a variety of devices for the manual filling of small numbers of capsules. These typically consist of sets of plastic plates that have sets of holes drilled in them corresponding to the size of the capsule that can be filled. The capsules are fed into the plates, either manually one at a time or in groups using a feeding device. The bodies are clamped in the bottom plate and the top plate removed, which separates the caps from the body. The bodies are released so that they sit below the top of the bottom plate. Powder or pellets are filled into the capsules by spreading material over the body plate. Normally, a spatula is used to aid material flow. A larger version of this machine is

Fig. 5 Schematic diagram of a dosing disk and tamping finger system (Bosch GKF machine): A) dosing disk; B) tamping finger; C) powder hopper; D) powder bed; E) support plate; F) tamp depth adjuster; G) over load relief spring; H) ejection adjuster; I) guide block; J) transfer block; K) powder plug; L) capsule body in bush; M) suction.

available, the Model 301, made in stainless steel by Chemical and Pharmaceutical Industry Co., Inc. This has a tamping device, which enables higher fill weights to be achieved.

A small-scale automatic machine, the In-cap[®], Dott. Bonapace (Schaefer Technologies, Inc.), is available. This machine measures the dose using a tamping finger and dosing disk device. The output is up to 3000 capsules per hour.

Instrumented Filling Machines

Instrumented capsule-filling machines are not in widespread use, unlike tableting machines (13). This is partly owing to the facts that less basic work has been done, that there is an inherent problem in measuring the low forces, (1–100 N) used in forming and ejecting plugs, and that the powder bed is less controllable than that a tablet machine (10). Most of the published studies have been on intermittent motion dosing tube machines. Strain gauges have been applied to the piston and LVDTs to the moving parts of the system to measure the work involved in plug formation (13). Only one group has published work on an instrumented dosing disk and tamping finger machine (14). The problem with these machines is that the plug is formed at up to five different positions, and full instrumentation would be difficult. Capsule-filling machine simulators have been constructed to overcome some of the problems inherent in putting instrumentation on actual machines. Rotary operation machines present the biggest problem because of the movement of the dosing parts. One novel solution was to use the machine turret, with a single dosator, held stationary, and to construct a rig that moved the powder hopper around the dosator, simulating machine-running (15). A conventional simulator for an intermittent motion dosator machine has been built that, in addition to the forces of axial compression and ejection, can measure the radial compression force (16). This has been used to study the consolidation and elastic properties of excipients. A tablet compaction simulator has been used to investigate plug formation at low forces and the results analyzed using standard tableting physics (17).

Dry Solid Filling

Granules, pellets, and tablets can be filled into capsules using automatic filling machines. Products are prepared in these forms to modify the release rates of active ingredients, to separate incompatible components, or to

densify a product to achieve the fill weight in a specific size of capsule.

The machines that can be used to fill these products can be divided into the direct and indirect categories. In the former, the material is fed into the body until it is completely full, e.g., Quali-fill Pellet Filler (Schaefer Technologies, Inc.) or any auger-filling machine with the auger removed. In the latter, the dose of material is measured in a chamber with a variable volume, which can be adjusted to give the required weight. Machines have modified dosators that either use suction to hold the material in the tube during transfer or are filled when they pushed up through the material bed. Other machines have special chambers with sliding plates to measure and release the material, e.g., Bosch GKF machines. After measurement, material is transferred to the capsule bodies either using gravity or assisted by air pressure, e.g., IMA Farmatic 2090 and MG2 G60.

The physical properties of these formulations are similar. Each type must be preferably nonfriable; tablets are usually film-coated. Two types of tablets are filled into capsules. Generally, the tablets are convex and have diameters that enable them to be introduced easily into the body and with sufficient clearance so that they do not tip onto their side (18). In the United States, after the Tylenol[®] incident in the 1980s, there is a need to fill large single tablets into a capsule so that there is no room for movement in the shell. The capsule shell is either banded or shrunk onto the tablet to prevent its removal. Granules and pellets should be regular in shape so that they flow and pack well. Their size should be related to the size of the capsule. Smaller-diameter pellets should be used for smaller capsules; otherwise, lower than expected fill weight will occur because of the “wall effect” of particle-packing (19).

Liquid Filling

All the major machine manufacturers have made machines that can fill capsules with liquids. There are two types of liquid fills: formulations of nonaqueous solutions and suspensions and formulations that are liquefied only for the filling process by either heat or shear stress (20). If the formulation is mobile at ambient temperatures, then the capsules will need to be sealed after filling.

The dose of material is measured using volumetric pumps, and thus the uniformity of fill is in most cases better than what can be achieved normally on a powder-filling machine. Typically, coefficients of variation of fill weight less than 1.0% are routinely achievable. This value will depend on the physical properties of the liquid,

particularly its viscosity (22). Filling machines have been made that can handle materials with viscosities from 100 cp to 20,000 cp. Liquid-filling machines operate mostly at slower speeds than do the equivalent powder-filling machines. This is because the liquid has to pass through a much smaller orifice than that for a powder and thus takes longer. The rates are typically 50–66% of the rated output of the same size powder-filling machine.

Capsule fill capacity

The fill capacity of a hard capsule is dependent on the physical size of the capsule, the type of formulation, and the dosing mechanism on the filling device (Table 2) (10). The fill weight for powders has historically been calculated by multiplying a powder density value by the capsule volume as provided by the capsule manufacturers. This capsule volume is in fact the volume of the capsule body only, because the value was derived from work at the beginning of the 20th century when capsules were filled by hand in pharmacies. The relationship gives a reasonably accurate forecast machine filling if this volume number is multiplied by the tapped bulk density (TBD) of the powder. The reason for this is the dosing mechanisms on filling machines. The dependant machines, which can fill the total internal volume of the capsule, are able only to pack the powder at densities less than the TBD of the fill. The independent machines, which are able to apply a higher compressive force to the powder, form plugs whose dimensions must be less than the internal diameter and length of the capsule (Table 2). Thus, although the density of the plug will be higher than the TBD of the fill, the machines are unable to fill the total internal capsule volume.

The same rules of packing apply to pellet- and granule-filling. The size of the particles is important because of the increase in voidage caused by large particles in a small diameter tube. The smaller the capsule size, the smaller the corresponding size of the particles should be to achieve uniform fill weights.

There is a restriction in the fill capacity for liquids in capsules. To prevent the spillage of product, the maximum fill volume should not exceed 80% of the body volume.

Capsule Sealing

Many methods have been proposed for the hermetic sealing of capsules to prevent the leakage of liquids. The method proven to be the most successful is gelatin-banding (20). Two bands of gelatin solution are applied around the center of the filled capsule e.g., HicapsealTM 40/100

Table 2 Capsule fill volume data

Size	Body volume (ml) ^a	Internal volume ^b (ml)	Max. plug length ^c (mm)	Max. plug volume ^d (ml)

(Schaefer Technologies, Inc.). This band is dried using air at ambient conditions to prevent moisture loss from the shells, which would make them brittle. The band can be colored, permitting a more complicated appearance for product branding. This band complies with the requirements of the FDA *Tamper-Evident Packaging Requirements for Over-the-Counter Human Drug Products* (21) for tamper-evident sealed capsules.

Multiple Contents

Automatic filling machines are available that can have more than one product dosing device. Therefore, combinations of materials can be filled into the same capsule, such a mixture of a powder and a semisolid formulation or a powder and a tablet. The same formulation rules apply as to single forms. Combinations of materials allow the formulator to achieve specific goals in terms of product stability and types of release.

FORMULATION

Powder Properties

Powder formulations for capsule-filling must have good flow properties, be nonadhesive, and be cohesive enough to form plugs at low compression forces. In addition, they must be stable and release the active ingredient in the desired manner. The filling properties can be assessed on the bench scale by using a variety of tests ranging from simple to complex (11). Successful correlations between

powders and filling performance have been made in several reports by determining various powder property constants calculated from tapped bulk-density volumetry (23–25). For various microcrystalline celluloses, Lüdde–Kawakita's constant a and Hausner's ratio were shown to be good indicators of machine-filling performance, especially when judging interchangeability of materials from various sources (23). Investigations on the packing properties of binary mixtures of different-shaped particles have shown that Lüdde–Kawakita's constant a can be used as an indicator of the maximum volume reduction (24). For microcrystalline cellulose, an angular particle, lactose monohydrate, improved packing, whereas spherical or needle-shaped particles tended to decrease the packing properties. The same methodology was used to investigate the bulk-volume changes of powders after granulation or low compression (25). This showed that capsule fill weights could be increased by high-shear granulation or by the use of machine compression and that the outcome was related directly to the initial powder properties. The filling of capsules with powdered herbs presents additional challenges because of the range of tissue materials used. The flow properties of these materials are poor, and a range of powder property constants was determined to try to find a parameter that correlated with filling-machine performance (26). It was found that tamp-filling machines were able to handle a greater variety of herbs than were dosator machines. The flow of powders under active conditions can be measured using specially constructed rheometers, and these data can be related to other powder properties (27).

The flow of powders on filling machine is aided by machine design. Most machines have devices to assist flow in the form of moving mechanical parts, vibration, or

suction pads. Another hindrance to obtaining good fill-weight uniformity on machines is adhesion of material to moving parts, particularly to the dose-measuring devices. It has been shown that the nature of the surface texture of the dosator is an important factor (28). The surface of the dosing parts can be coated with different metal finishes, similar to those used for tablet punches and dies, to reduce adhesion (29). The type of coating is related to the physical nature of the powder formulation.

In Vitro Testing

Pharmacopeias require that hard capsules be tested in the same apparatus as tablets, even though they have very different physical properties. Filled capsules contain entrapped air, and most formulations will float on water. Devices are required to ensure that they sink, and these can influence the results obtained (30). Gelatin and HPMC are adhesive materials and tend to block wire meshes that form part of the standard equipment. The manner in which capsules disintegrate and dissolve is dependent on several factors such as temperature and nature of the test media (31). The literature makes reference to the hard capsule effect; however, the literature shows that the rate-controlling step is the nature of the contents and not of the shell (32).

When capsules are placed in an aqueous solution at body temperature (37°C), the walls absorb water and swell (31). The rate of penetration is proportional to the thickness of the wall. In gelatin capsules, water droplets can be observed on the inside surface of the shell after 30–40 s. The wall ruptures first at the shoulders of the cap and body, which are the thinnest parts of the shell. The rate of gelatin solubility is dependent on the temperature of the solution (33). There is a significant decrease as the temperature falls below 35°C, and below approximately 30°C, they are completely insoluble and merely swell and distort. HPMC capsules, on the other hand, have a slower but uniform solubility between 10 and 55°C (34). The results for both types of capsules are influenced by the nature of the test media, e.g., the ionic strength of the ions present and the pH level (6, 31).

The rotating paddle method is the most frequently prescribed apparatus for measuring the dissolution rate of products in hard capsules. The test is used for manufacturing-control purposes and for assessing product stability. When gelatin capsules are stored at high temperatures and humidities (45°C, 75% RH), their solubility in water decreases with time. This is owing to the formation of a “pellicle” that slows release (35). This effect is called cross-linking and can be caused either by

interaction between gelatin and compounds containing reactive groups such as an aldehyde (36) or by reorientation of the gelatin molecules to a more collagen-like structure (2). In the early 1990s, the FDA became concerned with this and initiated a test program to measure whether this had an effect on product efficacy (37). They filled acetaminophen into capsules that had been stressed by treatment with formaldehyde at two levels and into unstressed shells. They measured the dissolution in water and in simulated gastric fluid (SGF), with and without pepsin. This produced three sets of results, those that passed in all media (unstressed shells), those that failed in water but passed in the SGF (low-stress formaldehyde), and those that failed in all media (high-stress formaldehyde). The capsules were tested in human volunteers. The pharmacokinetic parameters C_{\max} , T_{\max} , and lag times could be ranked in order and the Area Under the Curve (AUC) were identical. However, the products were not considered bioequivalent because the results from the capsules that failed all the dissolution tests were outside the 80–125% confidence limits compared with the unstressed capsules. From this study, the *U.S. Pharmacopeia* introduced a two-tier test for hard-capsule dissolution (36). If the capsule product fails in water, then the test can be repeated using either a solution at pH 1.2, containing pepsin, or one at pH 7.2, containing pancreatin. An additional study using γ -scintigraphy showed that there was no difference in disintegration in vivo between untreated and medium-stressed capsules (38).

HPMC does not react with aldehydes or other agents that cause cross-linking of gelatin (6). HPMC capsules start to release their contents slightly slower than do gelatin capsules because of the slower rate of diffusion of water through the shell walls. However, once dissolution has begun, rates are similar, and the results are comparable. There are only minor changes in their dissolution after storage under accelerated conditions (6).

In Vivo Performance

Capsule products can be formulated to deliver active ingredients to various sites along the gastrointestinal tract or to the respiratory system (39). Buccal products can be made by filling standard capsules with semisolid matrix formulations, which give the product good sensory characteristics that allow them to be chewed or sucked and the contents retained in the mouth for absorption or action (40). The capsule shape is good for swallowing because one axis is longer than the other. This enables the tongue to line it up like a torpedo for entry into the throat. Many large tablets are capsule-shaped, the so-called

caplet, to take advantage of this. The literature shows that, provided the patient takes the capsules with water while up right, they do not stick in the throat any more than and, in fact, probably less than any other solid dosage form (41, 42). Capsules can be visualized inside the patient either using radio-opaque markers and x-rays or using radioisotopes such as technetium-99 and γ -scintigraphy. In the stomach, they disintegrate, and the contents spread depending on the patient's feeding state, fed or fasting (43). Capsule products can be retained in the stomach by the use of floating formulations. These are based on the use of hydrocolloids that swell on contact with water, forming a gel that releases the active drug by diffusion (44). Enteric products can be made either by coating the capsule shell with a polymer, which has the correct pH solubility characteristics, or by filling the capsule with coated particles (39). The challenge facing many formulators is the delivery of small peptides and proteins to the colon. This can be achieved by coating capsules with polymers that will only be broken down in the colon, e.g., mixtures of an azopolymer and a methacrylate polymer (45). Delivery to the colon can also be achieved by using a fill that includes an organic acid and a combination of pH-sensitive coatings, which together deliver the active drug to the proximal colon (46). Capsules can be administered rectally. They can be formulated to give immediate or prolonged release (47). The administration technique is different for other solid rectal forms, and they need to be coated with a glidant such as liquid paraffin.

Powders for inhalation products have been filled into capsules, which function as an inert biodegradable package. The active ingredient is in a micronized state, and it is filled either directly into the capsule or, more frequently, is attached to a carrier particle such as lactose (48). The formulations are filled using automatic machines and because the fill weight is small, i.e., less than 40 mg, microdosators are used. The product is taken using a special inhalation device. Powder is released from the shell either through holes, which are punctured into it by the device, or by the capsule parts being separated inside the device. The inhalers are breath-actuated. When the patient inhales, there is a turbulent airflow through the device that carries the active particles into the lung (49).

Formulation for Release

Most products are formulated to release their contents into the stomach. The rate-controlling step for release is the nature of the contents inside the capsule (32). In preparing a formulation, a formulator needs to take into account the

physicochemical properties of the active ingredient, the nature and type of excipients required, and the filling process (10).

The properties of the active drug that are most significant are its aqueous solubility and particle size. The particle size needs to be chosen carefully. Smaller particles should dissolve faster because of their greater surface area but when filled inside a capsule they may aggregate, and the dissolving liquid may not be able to reach the individual particles (Fig. 6) (50). The available surface area of the active ingredient is more important than the actual surface area. Usually, the excipient that is the largest single quantity in the formulation is the filler (diluent), which functions both to increase the amount of fill material for potent actives and to aid in the formation of the powder plug. They can also play a role in the release of the active drug. People were first alerted to this in the late 1960s by the diphenylhydantoin incident in Australia, which showed that fillers need to be selected with solubility properties complementary to those of the active (51). Poorly soluble actives are best formulated with soluble excipients. The overall aim should be to make a powder mass that is as hydrophilic as possible. This can be done easily with potent actives because there is space available inside the capsule to accommodate excipients with the necessary properties, both in terms of flow and solubility. For higher-dose actives, excipients must be chosen that are active at low concentrations. Thus, disintegration and wetting agents need to be added. Excipients such as starch do not function as disintegrants in capsules as they do in tablets because the powder fill is much more porous. Sodium starch glycolate and croscarmellose, the so-called superdisintegrants, are used because of their greater swelling and wicking capability (52).

Certain excipients added to formulations to improve filling-machine performance can have an adverse effect on release because they are hydrophobic in nature. This is true of lubricants, which are added to formulations to prevent adhesion and to improve flow. The most used excipient in capsule formulations in both the United States and Europe is magnesium stearate (52, 53). This is hydrophobic, and there are many reports in the literature concerning its adverse effect on dissolution rates. However, the relationship between the concentration of magnesium stearate and release rate is not quite as simple as for tablets, in which an increase in amount brings a proportional decrease in release. The reason for this is the very different nature of tablets and capsules. A tablet is compressed using high forces to form a solid compact of relatively low porosity and must be if it is to survive subsequent handling. A hard capsule product, on the other hand, contains a powder mass of high porosity, which may

Fig. 6 The release of ethinamate from capsules containing different particle size fractions packed to give different porosities. A) The percentage of drug release after 30 min; B) The liquid permeability $\text{m}^2 \times 10^{11}$ of equivalent size fractions at known porosities. ●—● = 251–420 μm ; □—□ = 177–251 μm ; ○—○ = 152–177 μm ; +—+ = 66–76 μm ; ▽—▽ 8.3 μm . (Adapted from Ref. 50.)

or may not have been compressed into a plug, and is contained within the shell that can withstand handling. Magnesium stearate functions as a lubricant when it is dispersed on the surfaces of other particles. At this site, it also reduces the cohesion of particles, and thus as its concentration increases, the powder mass will become weaker. Several workers have shown that an increase in magnesium stearate concentration has increased dissolution rates: small particles are made less cohesive (Fig. 7) (54), and powder plugs are weakened, thus breaking apart more readily when the capsule shell has dissolved (Fig. 8) (55). If the level in the formulation is not optimized, then there is a possibility that during the filling operation, the magnesium stearate will be gradually dispersed to a greater extent, resulting in changes in dissolution or weight uniformity (10, 56).

The method to improve the release rate of poorly soluble actives by dissolving or suspending them in polyethylene glycol was first suggested in 1970 (57). Since then, the filling of semisolid matrix formulations for filling into hard capsules has been developed, which enables this simple concept to be turned into a practical application (20). This formulation technique gives a different means to control the release of active drug from a capsule, either improving or delaying release. The technique involves dispersing or dissolving the active drug in excipients that are available in a range of melting points and Hydrophile-Lipophile Balance values (20). It is possible to modify the release rate of an active ingredient from such a matrix

capsule by simply changing the properties of the single excipient (57). This technique has the added advantage that when working with potent and toxic material, it significantly reduces cross-contamination within an area (58). The actives once dispersed in a semisolid matrix are safe to handle without resorting to the use of expensive containment areas, i.e., any material that is spilt does not spread through the local environment, unlike a powdered material.

(Adapted from Ref. 55.)

Formulation Optimization and Expert Systems

Product formulations must meet a number of goals. They must be able to be filled by machines to give a uniform, stable product. They must release the active ingredients in a manner to give the desired therapeutic effects. They must comply with the regulatory and compendial specifications. The excipients used in formulations often have properties that aid in compliance with one aspect but, at the same time, can have a negative effect on another goal. The relationship among the factors is complex. There are a variety of statistical tools that can be used to optimize formulations to achieve the best values of all the factors (59).

Another method of obtaining the best formulation is to use a so-called expert system to devise a formulation. The computer software is based on the use of neural networks and knowledge-based systems (60, 61). They serve two functions. First, they are able to reduce development time by suggesting the probable formulations, and second, they act as a teaching tool to pass on the knowledge of experts in the field.

CHROMATOGRAPHIC METHODS OF ANALYSIS— GAS CHROMATOGRAPHY

Isadore Kanfer
Roderick B. Walker
Michael F. Skinner

Rhodes University, Grahamstown, South Africa

INTRODUCTION

History

The word “chromatography” is derived from the Greek words “chroma” and “graphein,” which mean “color” and “to write,” respectively, or “color writing.” The initial use of the term is attributed to Tswett (1), who separated colored bands of plant pigments on a chromatographic column that consisted of an adsorbant powder that was washed with a liquid solvent termed the mobile phase. Substitution of this liquid mobile phase by a gas constitutes the fundamentals of gas chromatography (GC), where the solute to be separated is vaporized and carried down the length of a tube that contains an immobile solid or liquid phase, i.e., the stationary phase. The gaseous mobile phase serves to move the solute vapors along the column at rates dependent on several factors, the most important of these being temperature.

The first reported use of a vapor as the mobile phase is attributed to Martin and Synge (2) in 1941. They used the principles of partition chromatography, whereas James and Martin, in 1952, described the first application of this method, gas–liquid chromatography (GLC), for the analysis of fatty acids and amines (3). Gas adsorption chromatography (GSC), on the other hand, involves the use of a solid stationary phase and separation is based on an adsorptive mechanism. This technique was first described in 1947 in a doctoral thesis by Prior (4), under the supervision of Professor Cremer, and subsequently in their 1951 publication (5).

It was not, however, until 1955–1956 that the first commercial gas chromatographs were built (6, 7). Rapid progress in instrumentation and increased use of GC followed with the introduction of novel detectors, such as the flame ionization detector (8, 9), development of the capillary column (10), and the introduction of temperature programming and microsyringes for sample injection (6).

Utility

The introduction of GC as an analytical technique has had a profound impact on both qualitative and quantitative analysis of organic compounds. Identification of compounds by GC can be accomplished by their retention times on the column as compared to known reference standards, by inference from sample treatment prior to chromatography (11), or by the concept of retention index (12). The latter method and tables of retention indices (13) with associated conditions have been reported (14). Although qualitative data and analytical techniques for identification of compounds are well-established (15, 16) and relative retention data for over 600 substances also have been published (17), the main utility of GC undoubtedly lies in its powerful combination of separation and quantitative capabilities. Use in quantitative analysis involves the implementation of two techniques being performed concurrently, i.e., separation of components and subsequent quantitative measurement.

The use of GC was first included in the United States Pharmacopoeia (USP) in the sixteenth edition (18) in 1960, and became an official method of the British Pharmacopoeia (BP) in 1968 (19). GC has found widespread use in pharmaceutical analysis by virtue of its applications to purity and control analysis of raw materials, content and quality assessment of dosage forms (including product stability), and in the quantitative measurement of drugs in biological fluids. The latter application is important for therapeutic drug monitoring, pharmacokinetic studies, and bioavailability assessments. In fact, in a survey on GC use (20), a major application of this technique was in the field of pharmaceuticals.

When this article was first written several years ago, it appeared that the advent and establishment of high-performance liquid chromatography (HPLC) in pharmaceutical analysis had somewhat diminished with the utilization of GC. However, new regulatory requirements for drug approvals by the Federal Drug Administration

(FDA) and other regulatory agencies around the world, more particularly with respect to the determination of organic volatile impurities (OVI's) as well as other impurities and related substances (20), has resulted in more extensive use being made of GC in modern compendia, such as the USP 24th edition (21) and the 1999 edition of the BP (22). Perusal of the current USP (21) indicates that many more GC applications have been introduced since the 22nd edition of the USP. New inclusions have been incorporated in the tables in this article. Similarly, the recent edition of the BP (22) also includes numerous new applications. A list of compounds in the BP (which includes the European Pharmacopoeia) that use GC is included separately as an Appendix.

GC remains the chromatographic method of choice for thermally stable volatile compounds and for drugs, which are difficult to measure by HPLC due to detector insufficiency and/or inadequate resolution by the HPLC technique. The use of capillary columns in GC makes the method particularly attractive for difficult multicomponent analysis since extremely high resolution can be readily attained.

Modus Operandi

As previously mentioned, GC is a two-phase system that consists primarily of a stationary (solid and/or liquid) and mobile (gas) phase. When a liquid stationary phase is used (GLC), the liquid is immobilized as a thin film supported on a finely divided, inert solid support usually consisting of siliceous earth, crushed firebrick, glass beads, or in some cases, the inner wall of a glass tube. In GSC, the stationary phase is an active adsorbent, such as alumina, silica gel, or carbon, which is tightly packed into a tube.

Separation of components takes place in this tube (chromatographic column) following the introduction of sample at the tube inlet, which is subsequently swept through the column, partitioning or being dynamically adsorbed (or both) between the stationary and mobile phases during transit. The degree and speed of separation of components is governed by several factors, such as temperature, gas flow rate, and the physicochemical properties of the individual components being separated, as well as those of the stationary and to a lesser extent, mobile phase. Obviously, therefore, molecules with greater affinity for the stationary phase will spend more time either adsorbed to or partitioned within that phase and thus take longer to emerge from the column.

On emerging at the outlet, each component passes into a detector system that produces a signal that can be related to the mass of the individual component being detected.

This signal is usually amplified electronically and subsequently recorded on a chart-recorder, integrator, or captured by an online data system. The resulting response is in the form of a signal–time plot or chromatogram, and is subsequently evaluated for either qualitative or quantitative use.

THEORETICAL PRINCIPLES AND RATE THEORY

A general account of chromatographic theory was presented in volume 2 of *Encyclopedia of Pharmaceutical Technology* (23). Therefore, the following discussion will focus specifically on GC theory. The separation of the component of a mixture depends upon the column performance (efficacy) and the relative retention capability of the stationary phase (selectivity). The former determines the width of the peaks relative to the length of time a component spends in the column, while the latter determines the relative position of each emerging component (resolution).

When the sample is introduced into the column, usually in the form of a zone of vapor, it takes the form of a narrow band. During transit through the column, various factors influence the width of this band, which is continuously increased due to various dispersion processes. These include diffusion of the solute, resistance to mass transfer between and within phases, and the influence of flow irregularities and perturbations (24). A simple concept, the “theoretical plate,” carried over from distillation processes, has been used to compare columns and account for the degree of dispersion that influences bandwidth. A chromatographic column may be considered to consist of numerous theoretical plates where the distribution of sample components between the stationary and mobile phase occurs. Hence, a measure of the efficiency of a GC column may be obtained by calculating the number of theoretical plates, N , in the column from:

$$N = 16 \left(\frac{t}{w} \right)^2 \text{ OR } N = 5.54 \left(\frac{t^2}{w_{1/2}} \right) \quad (1)$$

where t is the retention time of the substance, w is the width of the base of the peak obtained by extrapolation (tangential extension of the sides of the relevant peak) of the relevant peak to the baseline, and $w_{1/2}$ is the peak width at half height (Fig. 1).

The higher the value of N for a column, the more efficient it will be. Columns with high efficiency allow smaller samples to be injected into shorter columns at

Fig. 1 Chromatographic separation of two substances.

lower temperatures, which results in high resolution of components in less time.

Column performance under different conditions or the comparison of different columns may be assessed by considering the height equivalent of a theoretical plate (HETP). Thus, $HETP = L/N$ where L is the length of the column. Van Deemter et al. (25) derived an equation for dispersion in chromatography:

$$HETP = 2\lambda d_p + \frac{2\gamma D_g}{\mu} + \frac{8k' d_f^2}{\mu^2 (1 + k')^2 D_1} \mu \quad (2)$$

where λ is a constant related to the geometry of the column packing particles, d_p is the average diameter of the solid support particles, γ is a factor to correct for the "tortuosity" of the column's gas channels, D_g and D_1 are solute diffusion coefficients in the gas and liquid phases respectively, d_f is the liquid film (stationary phase) thickness, k' is the partition coefficient of the solute, and μ is the linear gas velocity (26). Therefore, the Van Deemter equation expresses HETP as a function of the average mobile phase velocity μ and for a specific column, the equation has the general form:

$$HETP = A + \frac{B}{\mu} + C\mu \quad (3)$$

where A is the eddy diffusion term that results from flow inequalities in the column packing, B is the molecular diffusion term (when divided by μ it reflects axial diffusion in the mobile phase), and C reflects resistance to mass transfer from the stationary phase. The linear gas velocity, μ may be obtained from:

$$\mu = \frac{\text{Length of column}}{\text{Retention time of an unretained component (e.g., air)}} \quad (4)$$

The flow dependence of the three terms in the Van Deemter equation gives rise to a hyperbola (Fig. 2) when HETP is plotted against μ for a single component. The

minimum is the flow rate at which the column will function at optimum efficiency. Fig. 2 also depicts how the A , B , and C terms contribute to the HETP. For maximum efficiency, these terms must be minimized, i.e., keep HETP as small as possible. Minimization of the A parameter is readily accomplished by using small uniform packing material particles in small diameter columns. Decreasing the particle diameter, d_p , lowers the HETP. However, below a certain particle size, flow of carrier gas through the column is restricted and results in pressure increases, which limits the reduction in particle size. Since λ is a measure of the column packing particle irregularities, the more uniform the size and shape of these particles, the smaller the value of λ .

The B parameter relates to the diffusivity of the solute in the carrier gas. Increases in molecular diffusion will result in increases in band broadening, which may, however, be controlled to some extent by increasing the

Fig. 2 Plot of HETP vs. flow velocity.

gas pressure. The use of a high-molecular-weight carrier gas will retard diffusivity and result in the best efficiency. However, detector function may be affected by the type of carrier gas used; hence, for the purposes of expediency, a compromise is often made by employing hydrogen or helium, which allows rapid analysis albeit with somewhat reduced efficiency. These aforementioned gases, which can rapidly diffuse into the stationary phase, are used at higher flow rates than nitrogen, another commonly used carrier gas.

The remaining parameter, C , is a measure of the mass transfer of the solute molecules from the stationary into the gas phase and depends upon several variables. These include the transfer of solute from liquid to gas and vice versa. Use of thin films of liquid phase will thus allow faster analysis at lower operating temperatures, although sample capacity will be reduced. Viscosity of the liquid stationary phase also affects mass transfer and therefore, should be kept as low as possible at the lowest possible temperature.

Golay (10) and Giddings (27), respectively, described a modification of the rate theory for capillary columns (hollow tube with inner wall coated with liquid phase) and the random walk, nonequilibrium theory. The former derived an equation to describe the efficiency of an open tubular column, while the random walk theory describes chromatographic separation in terms of statistical moments. The nonequilibrium theory involves a rigorous mathematical treatment to account for incomplete equilibrium between the two phases (28).

Selectivity is a function of the efficiency of the stationary phase with respect to its interactions with the solute vapor. Selection of an appropriate liquid stationary phase will even allow the separation of compounds that have the same vapor pressure. Separation is thus determined by the solubilities of the respective solutes in the stationary phase. Hence, the partition coefficient, k , is an extremely important parameter and is given by the following relationship:

$$k = \frac{\text{Concentration of solute in liquid phase}}{\text{Concentration of solute in gas phase}} \quad (5)$$

The efficiency of a stationary phase for a particular separation is measured by α , the relative retention, which is the ratio of two adjusted retention times (Fig. 1):

$$\alpha = \frac{t_2 - t_a}{t_1 - t_a} \quad (6)$$

where t_2 is the retention time of one of the components, t_1 is the retention time of a second or reference component in the mixture determined on the same column using the

same separation conditions, and t_a is the retention time for an unretained compound, such as air. It is thus seen that α reflects the ratio of the partition coefficients for two components being separated under identical conditions and is a useful parameter for the identification of compounds when one of the components is a reference standard material (21). In order to express how well two peaks are actually separated, a resolution term, R , may be determined from Fig. 1, i.e.,

$$R = \frac{2(t_2 - t_1)}{W_2 + W_1} \quad (7)$$

where t_2 and t_1 are the retention times of the two components, and W_2 and W_1 are the corresponding widths of the bases of the peaks. Resolution is a measure of both column and stationary phase efficiency and relates peak width and maximal separation. In order to obtain complete separation (baseline resolution) between two peaks, the value of R must be a minimum of 1.5.

SYSTEM COMPONENTS/EQUIPMENT

Gases

While in principle any gas may be used in GC as the carrier, a prerequisite stipulates that the gas be inert with respect to both sample and stationary phase at the operating temperature. The carrier gas plays a critical role in the separation process and indeed, contributes to the efficiency of the system, as was shown in the Van Deemter equation where HETP depends on solute diffusivity in the gas phase. In practice, however, the importance of this role is relegated to a somewhat lower priority since the choice of carrier gas is usually dictated by the detector requirements. Helium is the gas of choice for use with the thermal conductivity detector (TCD), and allows greater sensitivity as compared to nitrogen. The electron capture detectors (ECD), on the other hand, are more efficient when nitrogen or argon–methane mixtures are used as carrier gas, while no noticeable difference in sensitivity is evident between nitrogen and helium when using the flame ionization detector (FID) (29). Thermionic detectors (TD), such as the nitrogen–phosphorus detector (NPD) utilize nitrogen or helium as the carrier gas. Similarly, the photoionization detector (PID) uses oxygen-free nitrogen or helium, while nitrogen is used as carrier gas with the flame photometric detector (FPD). All gases used as carriers in GC should be of high purity. A report on carrier gas purity in GC has been comprehensively discussed by Perretta (30), and procedures for the

preparation of “clean” gases were published previously (31). Traces of hydrocarbons can lower detector sensitivity (FID), trace amounts of water can desorb contaminants in the column, which leads to high background signals and/or “ghost peaks,” while traces of oxygen can cause degradation of certain liquid phases, such as polyglycol and polyamides, which results in changes of solute retention times. Moisture can be removed by placing cartridges that contain an appropriate molecular sieve fitted in-line between the gas cylinder and the instrument. These type of filters also serve to remove other small, trace level contaminants, such as low-molecular weight hydrocarbons, and may be regenerated by heating with a slow flow of nitrogen for a few hours. Oxygen traps also should be used to protect stationary phases from oxidative degradation (32).

Flow Control

The carrier gas is fed into the GC via a pressure regulator, while flow controllers are used to control the mass flow rate. Maintenance of an accurate and constant carrier gas flow rate is essential for solute elution reproducibility in both qualitative and quantitative analysis. Normally, gas flow rates will decrease due to an increase in gas viscosity and column back pressure, with an increase in temperature, especially during temperature programmed work. Differential flow controllers are thus essential to assure a constant mass flow rate independent of the resistance of the column. In addition, detectors usually require gas flow control, and this can be accomplished using pressure regulators operating against flow restrictors. Gas flow rates can be simply measured at the end of the column with a soap bubble flow meter or by using rotometers. While flow control was previously adjusted manually, various manufacturers now offer software and associated hardware to effect such changes.

Sample Inlets

Various sample inlet systems have been designed with a primary objective of facilitating satisfactory vaporization of samples and subsequent transfer to the column as a compact “plug” in the shortest possible time and in an accurate and reproducible manner. Additional considerations for efficient sample introduction include maintenance of constant carrier gas flow rate and temperature during sample injection. Considerable differences, however, exist between the manner of sample injection and the actual injecting system, depending on whether packed columns or capillary columns are used. Therefore, sample volume considerations must be taken into account; whereas 1–10 μl is usual for packed columns, several orders of magnitude less is used with capillary columns. Inlet systems for packed columns usually consist of a heated injection block (Fig. 3) with a minimum dead volume port (to reduce band spreading) which is sealed with a special rubber septum through which the injection syringe needle may be inserted. Compounds which are thermally sensitive and unstable when in contact with metal surfaces may be protected by using glass liners that minimize the sample contact time with the metal injection block.

The foregoing discussion relates to the flash vaporization sample introduction technique that involves injection of sample into a precolumn zone that is kept at a temperature of 30–50°C higher than that of the column. This facilitates instantaneous sample vaporization. Samples also may be introduced by on-column injection where the sample is injected directly into the head of the column, which results in better precision than flash vaporization (33, 34).

Inlet systems for packed columns can often be used with capillary columns as well. However, the much smaller injection volumes and slower gas flow rates used with capillary columns, especially small-bore open tubular

Fig. 3 Injection block.

capillaries (0.25 mm i.d.), require different sampling techniques.

Split injection

Early capillary inlets utilize an inlet splitter, which splits the sample into two unequal portions, the smaller of which goes into the column. The major function of the inlet splitter is not only to redirect the amount of sample placed on the column but also to permit rapid flushing of the injection chamber so that the sample in the column is followed by pure carrier gas, thereby avoiding sample dilution (35). The larger portion of sample is vented out of the system and the ratio of the two flows, the split ratio, typically ranges from 1:10 to 1:500. Since split injection is a flash vaporization technique, the possibility of sample discrimination exists. All sample components must be divided in the same ratio irrespective of differences in molecular weight, component concentration, polarity, injected volume, and inlet temperature for optimum reproducibility. Although the discriminatory effect can be minimized through the use of different inlet configurations (36), quantitative results by sample splitting are often not as good as by splitless and on-column techniques.

Splitless injection

Splitless injection utilizes a “solvent effect” (37) and allows a relatively large amount of dilute sample (1–5 μl) to be injected. The sample is vaporized and then carried onto the column on which it must be reconcentrated prior to analysis. This is essential in order to prevent band broadening. In order to prevent column overloading, the amounts of components being separated should be less than 50 ng. The large excess of solvent used to prepare the sample is backflushed 30–60 s after injection in order to minimize the occurrence of a long solvent tail, which can obscure any early eluting peaks. There are two mechanisms for reconcentrating the solutes at the head of the column. Grob and Grob (38) utilized the “solvent effect,” whereby the solvent acts as a barrier to the sample components, which facilitates their condensation and concentration at the head of the column. This is due to the fact that when the sample components encounter a liquid phase mixed with retained solvent, the front of the sample plug undergoes stronger retention than the rear of the plug. In order to minimize column deterioration that can result from solvent overloading, a solvent in which the liquid phase is not readily soluble should be used. Both dichloromethane and hexane have been widely used and care should be taken to see that the initial column temperature is 10–30°C below the boiling point of the solvent selected.

Another method of reconcentrating the components at the head of the column is to keep the column temperature low enough to condense the solutes (cold trapping) (35). A general guideline for the use of this precolumn concentration technique is that compounds with boiling points 100°C higher than the column temperature will be cold trapped. Therefore, splitless injection should be used when component concentrations are too low for detection by split injection ($< 0.1\%$ sample) or when only a very limited amount of sample is available.

On-column injection

When dealing with thermolabile compounds, vaporization of the sample can result in degradation during this process. Schomburg et al. (39) described an on-column injection technique whereby the sample never encounters temperatures higher than the column temperature. This method also has been shown to be extremely useful for the separation of compounds that have low volatility and samples that have a wide boiling range. Using very fine long fused silica needles attached to a microsyringe and inserted into the capillary column bore, on-column systems have been described (40). The fine needles are too fragile for normal septum piercing, hence other methods have been devised in which a septum-free valved inlet is used (41).

Inlet modifications that incorporated air-cooling of the column inlet were later designed to overcome vaporization in the needle that resulted from the slow injections necessary to achieve a narrow band of injected sample (42).

Automatic injection

The injection process has been automated, thus facilitating batch processing of large numbers of samples that are completely unattended. Various automatic injector systems are commercially available for use with both packed and capillary columns. These are mainly based on the use of syringe injection and pneumatically operated under microprocessor control. Injector loops are largely used for the introduction of gases into the column, while manual injection continues to be extensively used. In the latter instance, the operator's injection technique can dramatically influence the quality of the analysis (35). A skilled operator may achieve precisions of the order of $\pm 1\%$ with manual syringes by careful debubbling of the syringe, and using sample sizes at least 50% of the syringe capacity to minimize needle hold up and setting errors, as well as using a very reproducible injection technique. However, the advent of automatic samplers considerably enhances injection precision and accuracy. In addition, the tedious process of carefully cleaning and flushing the syringe

between samples to avoid cross-contamination during manual injections is readily accomplished automatically.

Oven and Temperature Controls

The column is usually suspended in an insulated thermostatically controlled air oven through which the air is very rapidly circulated by means of fans or pumps. This allows accurate temperature control to within 0.1°C and minimizes thermal gradients. Provision is also made for the temperature to be rapidly increased and for the equally rapid cooling required with temperature-programmed work.

Injection port temperatures for packed columns include thermostatically controlled heating. These parts should be hot enough to rapidly vaporize the sample in order to prevent a loss in efficiency from the injection process. Heated detector systems also are used depending on the type of detector, to prevent sample condensation, which inevitably will result in peak broadening and loss of component peaks. Temperature control imparts stability to the detection system, often reducing noise and enhancing the detection limit. When the FID is used, its temperature must be kept high enough to avoid any water or by-products formed during the combustion process.

Detectors

A large variety of detectors have been designed for use in GC. In addition to numerous publications, several books and reviews that discuss the design and operating principles of GC detectors have been published (43–46).

The chromatographic detector, placed at the column exit, constantly monitors the emitted gas, and generates an electrical signal that is amplified and appears as a plot of detector response versus time, i.e., the chromatogram. Detectors may be “universal,” which responds to every eluted component (TCD), “selective,” which responds only to certain functional or elemental characteristics of the analyte (ECD and FID), or “specific,” which provides qualitative information concerning the structure of the eluting component (FPD). However, for classification purposes, GC detectors generally fall into one of two groups: concentration-dependent and mass rate-dependent detectors. The former, which includes the TCD and ECD, produces a signal that is proportional to the concentration of the sample in the carrier gas. In the latter (e.g., FID), the detector signal is dependent on the mass of sample that flows through the detector per unit time (g/s). Some of the most important properties relating to detectors are: 1) their sensitivity, which is a function of the amount of

component present in the injected sample; 2) their signal noise, which refers to random, short-term detector response and which combined with sensitivity, determines the detection limit for a given component; 3) their linearity of response, which indicates the region over which the detector signal is directly proportional to sample concentration or mass flow rate. The dynamic linear range of the detector is the range of sample size for which a signal is detected as a linear function of the sample size. Thus, a wide linear range is useful for quantitative analysis of multicomponent mixtures. In contrast to short-term noise, which depends upon electrical factors, temperature sensitivity, or flow variations, long-term noise is manifested by baseline drift in the chromatogram.

Detectors commonly used in GC and specified in the USP (21) include FID, alkali FID (NPD, TD), ECD, and TCD. A description of these detectors, including their operational principles and relative performance, was presented in a previous volume of this encyclopedia (23). Various other useful detectors for GC include photoionization (PID), flame photometric (FPD), electrolytic conductivity (ELCD), redox (RCD) and sulfur chemiluminescence (SCD), and helium ionization (HID) (47). Table 1 summarizes some of the features of detectors used in GC.

In addition to the above, several newer and highly sophisticated detection techniques that involve the coupling of various types of spectrometers with GC have emerged. These “hyphenated” techniques include the on-line interfacing of mass spectrometers (GC–MS) (57–60), infrared spectrometers that incorporate Fourier transformation techniques (FTIR–GC) (61), and FTIR–GC–MS (62). Generally, these are considered specific detectors mainly used to obtain qualitative information, although quantitative data can be obtained when operating a GC–MS system in the selected-ion-monitoring mode (SIM). This mode, in contrast to the normal scanning mode used for qualitative purposes, allows a single or a few characteristic ions of an analyte to be monitored and subsequently determined quantitatively (63, 64). Triple–quadrupole MS/MS spectrometers are becoming more prevalent and these are being increasingly coupled to GC's that provide enhanced quantitation capabilities (60).

Columns

The suitability of a column for a particular use depends on various factors, such as stationary phase, solid support, column tubing material, inside diameter, percent liquid loading, and temperature. Columns may be prepared in

Table 1 Detector features

Detector	Classification	Response	Recommended carrier gas	Applications	Approximate detection capability (g)	Comments
TCD	Concentration	Universal	Hydrogen or Helium	Most compounds including water	$10^{-6} - 10^{-8}$	Although less sensitive than other detectors, it is useful for moisture determinations (48), can detect some compounds
FID	Mass-flow	Universal	Argon, Helium or Nitrogen	Most compounds excluding water	$10^{-10} - 10^{-11}$	unresponsive to FID and is non destructive and thus useful for preparative work Lack of response to water and carbon disulfide allows these to be used as solvents without interference with the analysis
ECD	Concentration	Selective	Hydrogen, Nitrogen or Argon/5–10% Methane	Compounds with high electron affinities, e.g. halogens	$10^{-12} - 10^{-14}$	Good for electronegative compounds such as those containing extensively conjugated pi-electron systems, nitro- and highly conjugated aromatic compounds and compounds which can be readily derivatized to respond (49). Response depends also upon carrier gas flow rate
NPD	Mass-flow	Selective	Hydrogen, Helium or Nitrogen	Compounds containing nitrogen or phosphorus	$10^{-12} - 10^{-13}$	Can be used in the flame or flameless mode. In the latter instance, a very low fuel (hydrogen) flow is used to form a plasma around a heated bead of potassium or rubidium salts. This results in a reduced response to hydrocarbons and subsequently less interference. Halogens as well as organolead compounds respond to the NPD detector in the flame mode. Phosphates (from cleaning detergents), chlorinated solvents and silanizing reagents can deplete the alkali beads and should thus be avoided (50)
PID	Concentration	Universal	Helium or Nitrogen	Compounds with ionization potentials <12eV	2×10^{-12}	Carrier gas must be free of oxygen and hydrocarbons to avoid a loss in sensitivity and interference, respectively. Water, sulfur dioxide, saturated hydrocarbons smaller than hexane, chloroform, methylene chloride, ethylene chloride and acetonitrile are not detected. The detector is non-destructive and can detect low levels of inorganic compounds. (51)

(Continued)

Table 1 Detector features (Continued)

Detector	Classification	Response	Recommended carrier gas	Applications	Approximate detection capability (g)	Comments
FPD	Mass-flow	Selective	Hydrogen or Nitrogen	Phosphorus and sulfur compounds	2×10^{-10}	Operated with a flame, photomultiplier tube and either a 393 or 526 nm bandpass filter for sulfur or phosphorus detection, respectively (52)
ELCD	Concentration	Selective	Helium or Nitrogen	Sulfur, nitrogen and halogen compounds	10^{-12} – 10^{-13}	Following pyrolysis of column effluent, unwanted species are removed and the relevant products mixed with a liquid (alcohol/water) and differential conductivity subsequently measured. Depending upon the reaction gas used and whether the process is reductive or oxidative, specificity for nitrogen, sulfur or halogen compounds can be obtained (53)
RCD	Concentration	Selective	Helium	Compounds that react chemically to emit photons	2×10^{-11}	As with the ELCD, post-column treatment of the effluent is involved. The RCD responds to compounds that serve as reducing agents, such as alcohols, aldehydes, olefins, and carboxylic acids, and it is insensitive to many potentially interfering compounds such as water, oxygen, hydrocarbons and carbon dioxide (54)
SCD	Concentration	Specific	Helium	Compounds containing a sulfur—carbon bond	10^{-11} – 10^{-12}	Amenable sulfur compounds are reacted with fluorine to produce HF and the chemiluminescence is subsequently measured. Saturated hydrocarbons, methylene chloride, acetonitrile, methanol and carbon tetrachloride give little or no response (55)
HID	Mass-flow	Universal	Helium	Trace impurities in bulk gases and liquids	10^{-12} – 10^{-14}	The helium carrier gas must be at least 99.9999% pure for optimum sensitivity. Useful to detect nitrogen oxides, sulfur gases, alcohols aldehydes, ketones, hydrocarbons and water (56)

various lengths and diameters depending on the particular objective. Preparative columns may range from 0.95 to 10 cm (3/8–4') in diameter or larger for the collection of quantities of individual components when volumes between 0.5 ml and more are injected. Analytical (or packed) columns generally have outside diameters of 3, 4.7, or 6.25 mm (1/8, 3/16, or 1/4'), and inside diameters of 1–4 mm, while capillary columns with very narrow inside diameters are used for applications that require very high resolution. The inside diameter of the tubing is, in fact, one of the most critical column dimensions in determining the efficiency of separation.

Although packed GC columns may be made from various materials, such as glass, nickel, stainless steel, copper, aluminum, or even Teflon[®], the USP (21) and BP (22) recommend that glass or stainless steel columns be used for pharmaceutical analyses unless otherwise specified. The advantage of using glass lies in its relative inertness as compared to metal columns, although its fragile nature is certainly a disadvantage. In order to assure further the inertness of glass, silanization of the inside walls with 5–10 vol% dimethyldichlorosilane in toluene is often performed (65).

Capillary columns are usually fabricated from fused silica, with a polyamide outer coating to impart flexibility and reduce breakage during handling. These columns can be classified into three categories according to the size of the internal diameter. Typical inside diameters are 0.53 mm, 0.32–0.22 mm, and 0.2–0.1 mm for megabore (wide-bore), normal bore (high-resolution), and microbore (high-speed), respectively.

The selection of a stationary phase is extremely important in GC since it is the major controllable variable of selectivity in the separation process. Stationary phases can be nonpolar, polar, or of intermediate polarity. Cyclodextrins, cyclic oligosaccharides composed of varying numbers of glucopyranose units, were found recently to be extremely useful for the separation of chiral compounds (66). Three types of derivatives, 5-hydroxypropyl (hydrophilic), dialkyl (hydrophobic), and trifluoroacetyl (intermediate) have been used, each of these phases having a selected area of specificity.

Capillary columns offer many advantages in terms of speed of analysis, high resolution, and overall very high separation efficiency. New applications that involve the use of capillary columns are included in the USP (21). In particular, methods for OVI analysis prescribe, almost exclusively, capillary columns, whereas approximately 20% of the other GC methods also prescribe such columns.

Solid supports should be chemically inert and exhibit a large surface area. Support materials used are diatomaceous earths, Teflon[®], glass beads, and various polymers.

Since the surface of the diatomaceous materials consist of silanol (Si—O—H) and siloxane (Si—O—Si) groups, compounds capable of hydrogen bonding (alcohols, acids, amines, etc.) can interact with these media, which results in tailing. This problem may, however, be minimized by silanization (65) following extensive acid washing to remove inorganic impurities. Acid-washed flux-calcined diatomaceous earth is often used for drug analysis.

Specially treated glass beads have been used as supports for high-molecular-weight compounds. The beads are usually etched and silanized prior to coating with the liquid phase. Teflon[®] is a useful support material for the analysis of short chain polar substances, which tail on diatomaceous supports, and is particularly indicated for the analysis of corrosive substances such as halogenated acids.

When a separation can be effected by a purely adsorptive mechanism (GSC), various adsorbants and porous polymers are used. Commercially available adsorbants include silica gel, activated charcoal, and molecular sieve materials. These adsorbants are used mainly for the analysis of gases and low-molecular-weight, low-boiling compounds (67).

Porous polymers also are useful for gas analyses and for very polar molecules, such as amines, glycols, and acids. Copolymers of styrene and divinylbenzene and others, such as ethylvinylbenzene–divinylbenzene, cross-linked acrylic ester, vinylpyridine, pyrrolidone, and ethylene glycol dimethacrylate, are commercially available (29).

Open tubular columns are simply capillary tubes in which the inside of the column wall is used as the support for the liquid phase. These wall-coated open tubular columns (WCOT) have the stationary phase distributed in the form of a thin film on the inside surface of the open capillary tube, the walls thus serving as the support. In order to reduce the thickness of the liquid phase film, a porous layer may be formed on the inside wall of the capillary tubing and then coated with the liquid phase to produce a support-coated open tubular column (SCOT). Porous-layer open tubular columns (PLOT) are similar to SCOT columns, the difference being that in the former, the stationary phase is deposited on fine crystalline particles or glass powder which is adsorbed onto the walls of the tube. In both cases, the available surface area of the wall is increased, and allows an increased amount of liquid phase to be accommodated in the same length and diameter of tubing. The whisker-walled (WW) column consists of whiskers chemically etched on the surface of the wall, which also result in a significant increase in the available surface area. Wall-coated, porous-layer, and support-coated capillary columns are all available as whisker-walled, i.e., WWCOT, WWPLOT, and WWSCOT, respectively.

The stationary phase film thickness of capillary columns range from about 0.1–10 μm and can be divided into three film thickness ranges. Thin-film columns are usually 0.1–0.2 μm and offer the greatest stability. They have smaller sample capacity as compared to the thicker films but are the best for use with high temperatures. Thick films are usually 0.6–10 μm and allow higher sample loading, better retention for volatile compounds, and a high degree of inertness. Their main drawback, however, is larger bleed at high temperature as compared to the thin film type. The medium film thickness is about 0.3–0.6 μm and is a useful compromise in terms of sample capacity, retention properties, and phase stability.

In addition to the open tubular capillary columns, packed capillaries, and even micropacked capillaries, are commercially available. These columns contain support material, have internal diameters that range from 0.6–1.0 mm, and have the main advantage of being able to handle larger sample loadings. This is useful since direct analysis, as opposed to split-analysis, can be used with very short columns that operate at relatively high efficiency.

Column lengths of 0.3–6.1 m (1–20 ft) are commonly used and configurations can be straight, U-shaped, spiral, or flat coils. Straight and U-shaped columns are purported to be slightly more efficient than the coiled types. However, the dimensions of the GC oven usually dictate the choice. Capillary columns are generally much longer than packed columns and range in lengths from 10–100 m for the open tubular type and 1–6 m for packed type.

SEPARATION TECHNIQUES

Gas chromatographic analysis can be performed at constant temperature (isothermal mode) or with the column temperature increasing with time (temperature programming).

Isothermal

In isothermal GC, peak width increases linearly with retention time (68) and retention time increases exponentially with carbon number in a homologous series. In contrast, the peak width remains constant in programmed-temperature gas chromatography (PTGC) and retention times increase only linearly with carbon number in a homologous series (69).

Gas chromatographic methods for the analysis of impurities in pharmaceutical dosage forms and raw materials generally make use of isothermal techniques

where the temperature of the instrument is maintained constant throughout the run. However, when complex mixtures that contain components with widely different boiling ranges need to be analyzed, PTGC is undoubtedly the method of choice. Separation of components in such a mixture may prove difficult if at all possible under isothermal conditions. Using a high temperature for the analysis may result in poor resolution between the rapidly eluting volatile components. On the other hand, operating at a lower temperature could cause excessively long retention times for the less volatile compounds, with resulting peak broadening leading to poor detectability and prolonged running times.

Temperature Programming

The advent in 1952 of PTGC (70) and the subsequent introduction of commercial equipment for temperature programming provided the necessary means to analyze complex mixtures that contained components of widely differing boiling points and solved some of the problems previously described in the section dealing with isothermal separations.

The PTGC technique involves increasing the column temperature at a preset rate during the elution process. This rate may be constant throughout the run, or periods of isothermal operation may be automatically programmed at set times between temperature increases. Generally, the electronically controlled ovens are designed to increase temperature at rates from 0.5–30°C per minute. The initial temperature should be chosen to minimize the retention time for the least retained solute, while the final temperature must be sufficient to elute the least volatile compound in a reasonable time. The instrument then automatically resets the temperature to the initial value in preparation for the next sample.

A major problem with PTGC, however, is that column bleed may cause baseline perturbations as the temperature increases, which results in interference with the analysis. Compensation for this effect is usually accomplished by using a dual column/dual detector system or replacing the liquid stationary phase with another less volatile coating. In the former instance, the output signal from the reference column is used to cancel out the bleed from the analytical column. Electronic compensation using single-column, single-detector systems are also available, as are GC's with electronically controlled programmed gas flows. In the latter case, the carrier flow rate is increased during the analysis, which results in reduced baseline drift by avoiding or reducing column bleed. Since lower temperatures can be used, the analysis of thermolabile

compounds is facilitated and a wider range of liquid phases can be used.

Special Techniques

Various compounds do not readily lend themselves to analysis by GC by virtue of several factors, such as nonvolatility, instability, elicitation of poor detector response, or high adsorptive properties (presence of polar groups). These problems sometimes can be overcome by the use of pyrolysis or by derivatization. The former technique involves high temperature decomposition of high-molecular-weight, nonvolatile substances to lighter, and more volatile compounds.

Derivatization is a valuable aid in GC. Suitable derivatives may be produced using synthetic organic reactions such as esterification, acylation, and silylation (29). These methods serve to increase thermal stability in unstable compounds, improve detectability in some instances (e.g., derivatives for electron capture detection) and often sensitivity, improve volatility in instances where the parent compound is relatively non-volatile, and mask polar groups to reduce adsorption. Several comprehensive reports and reviews on derivatization have been published over the years (71–74).

Quantitative and Qualitative Analysis

GC constitutes an analytical technique whereby the separation of components in a mixture and their quantitative and qualitative assessment can be performed simultaneously.

The area under the component elution peak is proportional to the concentration of that particular component. Various methods can be used to measure this area and are based on the assumption that the shape of the peak is Gaussian. Electronic integration is the preferred method since very accurate and precise measurements are obtained this way ($RSD \leq 0.5\%$).

Peak heights may be used but are less reliable since any variability in temperature and/or flow rate will affect this measurement. Peak areas may also be calculated by multiplication of the peak height and the width at half-height. This gives a value equal to 84% of the true area (75). Triangulation, planimetry, and cutting and weighing also can be used to measure peak areas.

In order to minimize the possibility of errors as a result of variable injection volumes, the internal standard (IS) method should be used. It involves the addition of a

compound, the IS, which is not already present in the sample. This is normally a substance that elutes at a position near the sample component of interest and should be well resolved and readily detected under the given chromatographic conditions. The IS is added in constant amount to solutions that contain varying amounts of the analytical standard. Calibration curves are then constructed by plotting the ratio of either the areas or peak heights of the two peaks (analyte/IS) versus amount or concentration of analyte. The amount or concentration of each chromatographed sample can then be obtained by interpolation of the calibration curve. The calibration plot should be a straight line with an intercept of zero. However, nonlinear standard curves may result when the linear range of the particular detector is exceeded due to excess analyte concentration. The presence of high background and/or interfering compounds results in plots that have a positive intercept, while negative intercepts are usually indicative of sample loss during handling.

In contrast to the IS method, external standardization may be used in which several standard solutions of varying concentrations of the sample are prepared. Following constant volume injection of each standard solution, a plot of peak area (or height) versus concentration is made, and unknown sample concentrations are obtained from interpolation of the calibration curve. The success of this technique, however, is dependent upon the precision of injection volume, readily accomplished with automatic injection but less so when manual microliter syringes are used.

A further quantitative measure, normalization, is sometimes utilized to determine the proportion of one or more components in a mixture. This involves calculating the ratio of the individual component peak area to the sum of the areas of all component peaks in the chromatogram. It assumes that all the components have identical response factors to the detector. This is a reasonable assumption when all the components of the mixture are chemically similar. When structurally dissimilar components are analyzed, a response factor correction should be used by measuring the peak area for a known quantity of pure material and calculating the respective response factor (F) from:

$$F = \frac{\text{Component amount}}{\text{Peak area}} \quad (8)$$

Acquisition of qualitative data may be obtained by using specific detectors such as GC–MS, FTIR–GC, and FTIR–GC–MS, as well as from relative retention times or by the concept of retention index (vide infra).

Headspace Analysis

Specifications for pharmaceutical compounds, in addition to the actual active ingredient itself, include information and limits relating to the intermediates, residual solvents, and other volatile impurities (21) associated with their preparation.

Headspace analysis is a very effective technique for the analyses of volatile compounds, and is particularly valuable when direct injection would ruin the column due to corrosive or highly nonvolatile components present in the sample. Headspace analysis obviates extensive sample preparation, eliminates the possibility of unwanted component interference, and avoids degradation of susceptible components in the injection port or on the column (76).

The liquid or solid sample is placed in a vial, which is sealed with a septum and heated to a predetermined temperature for a period of time. Equilibrium between the sample and vapor phase is then established and a portion of the volatiles in the gas phase (headspace) is subsequently injected onto the column. Several different methods have been used to transfer headspace volatiles into the GC, from manual withdrawal that uses a gas syringe, to sophisticated automatic sampling that involves transfer lines, and valves that lead directly onto the column.

Two main techniques, however, may be used. These are static and dynamic sampling. The static method allows the temperature of the sample container to be held for a sufficiently long period to allow the gas-phase and sample-phase to equilibrate. The dynamic sampling uses an inert gas that is swept over or through the thermostated sample for a period of time sufficient to extract most or all of the volatile components. A general chapter on OVI's, in which five OVI's are specifically mentioned (chloroform, dichloromethane, benzene, trichloroethylene, and dioxane), was introduced into the USP (21). Previously, the USP included methods II and III, which provided an alternative to direct injection and specified dynamic headspace sampling. These, however, have now been excluded and method IV provides for the general use of static headspace sampling (77). Method VI, while still included, prescribes analysis by direct injection into a gas chromatograph, but none of the monographs in the USP or National Formulary (NF) specify use of method VI for OVI testing. The trend, it appears, has been toward using method IV as a replacement for other methods in individual monographs and that monographs that now specify method IV, originally specified method VI (78). The advantages, sampling techniques, and problems associated with headspace sampling were previously discussed by Hinshaw (79).

PHARMACEUTICAL APPLICATIONS

Applications of GC to the analysis of pharmaceuticals have been described in several books, compendia, and the review of Jack (80) to which the reader is referred. In addition, the reader might want to review the three-part multi-authored series (81) that includes HPLC determinations, as well as the comprehensive listing of published chromatographic methods in a book edited by Adamovics (82).

Although HPLC has largely superseded GC as the compendial chromatographic method of choice for the assay of pharmaceuticals, the application of GC continues to be an important and valuable analytical method for monitoring certain impurities and for the determination of various related substances and OVI's in many pharmaceutical dosage forms, as well as in raw materials. GC, furthermore, continues to be a valuable tool for the analysis of drugs in biological fluids for the purposes of therapeutic drug monitoring, pharmacokinetic studies, and in the assessment of bioavailability/bioequivalence.

A large number of pharmaceutical compounds can, however, be analyzed by either GC or HPLC. In terms of cost effectiveness, given that the equipment is available, GC often may be preferred due to its advantage of avoiding the use of expensive solvents and associated subsequent disposal problems.

Raw Materials (Bulk Drugs) and Dosage Forms

Both the USP/NF (21) and the BP (22) utilize GC for the following types of determinations:

1. Assay.
2. Chromatographic purity.
3. Identification.
4. Presence of volatile matter, intermediates, and related substances.
5. Water.
6. Presence of isomers, isomeric purity, and racemate ratios.
7. Alcohol content.

Tables 2–11 list the various compounds and the associated USP tests, together with their relevant chromatographic conditions. Drugs and related dosage forms have been arranged alphabetically, while descriptions of the various GC supports and liquid (coating) phases largely correspond to the abbreviations used in the USP. These are given starting on page 409:

Table 2 Compendial applications of GC for the assay of pharmaceutical raw materials and dosage forms

Material/dosage form	Column	Carrier gas	Temp. (°C)	Detector	Internal standard	Reference
Acetone	1.8 M × 3 mm I.D. S4	Helium	110–220 8/min	FID	None	NF (19, p. 2409)
Acetyltributyl Citrate	30 M × 0.32 mm I.D. Column Bonded with G42 (0.5µm)	Helium	80–220 20/min	FID	None	NF (19, p. 2409)
Amantadine Hydrochloride capsules	Glass, 1.22 M × 2 mm I.D. 10% G1/S1A	None	115	FID	Naphthalene	USP (24, pp. 103 and 104)
Amantadine Hydrochloride syrup	(100–120 mesh)	Specified				
Amitraz Amitraz concentrate for dip	1.5 M × 4 mm I.D. 3% G1/S1A	Nitrogen	250	FID	Squalane	USP (24, p. 121)
Amylene Hydrate	Glass, 2 M × 4 mm I.D. S2	Helium	190	TCD	None	NF (19, p. 2414)
Atropine Sulphate ophthalmic ointment	Glass, 1.8 M × 2 mm I.D. 3% G3/S1AB	Nitrogen	225	FID	Homatropine	USP (24, p. 179)
Atropine Sulphate ophthalmic solution					Hydrobromide	USP (24, p. 179)
Atropine Sulphate tablets	Fused Silica 25 M × 0.32 mm Capillary coated with G1	Helium	200–280 4/min	FID	None	USP (24, p. 181)
Avobenzene	Glass, 1.2 M × 4 mm I.D. 3% G3/S1AB	Helium	215	FID	Homatropine	USP (24, pp. 199, 200 and 201)
Belladonna extract						
Belladonna extract tablets						
Belladonna leaf						
Belladonna tincture						
Benzocaine and Menthol topical aerosol	1.8 M × 2 mm I.D. 10% G16/S1AB (for Menthol)	Helium	170	FID	Decanol	USP (24, p. 208)
Benzyl Alcohol	Glass or Stainless Steel, 1.8 M × 3 mm I.D. 5% G16/S1	Helium or Nitrogen	140	FID	Phenol	USP (24, p. 1865)
Butabarbital	1.8 M × 4 mm I.D. 10% G37/S1AB		260	FID	Tetracosane	USP (24, p. 261)
Butabarbital Sodium elixir	Glass, 0.9 M × 4 mm I.D. 3% G10/S1A (80–100 mesh)	Nitrogen	200	FID	Secobarbital	USP (24, p. 262)
Butabarbital Sodium tablets						
Butane	Aluminum, 6 M × 3 mm I.D. 10% liquid G 30/S1C	Helium	33	TCD	None	NF (19, p. 2422)
Burylated Hydroxyanisole	Stainless Steel, 1.8 M × 2 mm I.D. 10% liquid G26/S1A	Helium	175–185	FID	4-tert-butylphenol	NF (19, p. 2422)
Castor Oil emulsion	Glass, 1.8 M × 4 mm I.D. G25/S1	Helium	245	FID	Di(2-ethylhexyl) phthalate	USP (24, p. 323)
Cetostearyl Alcohol	2 M × 3 mm I.D. 10% liquid G2/S1	Helium	205	FID	None	NF (19, p. 2434)

Table 2 Compendial applications of GC for the assay of pharmaceutical raw materials and dosage forms (*Continued*)

Material/dosage form	Column	Carrier gas	Temp. (°C)	Detector	Internal standard	Reference
Cetyl Alcohol	2 M × 3 mm I.D. 10% liquid G2/S1A	Helium	205	FID	None	NF (19, p. 2435)
Chlorobutanol	Glass or Stainless Steel, 1.2 M × 3 mm I.D. 5% G16/S1A	Helium or Nitrogen	110	FID	Benzaldehyde	USP 24, p. 1865
Chloroxylenol	Glass, 1.8 M × 4 mm I.D. 3% G16/S1A	Nitrogen	210	FID	None	USP (24, p. 391)
Clindamycin Palmitate Hydrochloride	Glass, 0.6 M × 3 mm I.D. 1% G36/S1AB (80–100 mesh)	Helium	290	FID	Cholesteryl Benzoate	USP (24, pp. 431 and 432)
Clindamycin Palmitate Hydrochloride fororal solution						
Clioquinol	Glass, 1.83 M × 2 mm I.D. 3% G3/S1AB (80–100 mesh)	Helium	165	FID	Pyrene	USP (24, pp. 435 and 436)
Clioquinol cream						
Clioquinol ointment						
Clioquinol and Hydrocortisone cream						
Clioquinol and Hydrocortisone ointment						
Cyclomethicone						
Desflurane	3.66 M × 3 mm I.D. 20% liquid G1/S1A (60–80 mesh)	Helium	125–320	8/min	None	NF (19, p. 2443)
Dibutyl Sebaccate	Stainless Steel, 3.7 M × 2.4 mm I.D. 10% G31 and 15% G18/S1A	Helium	80–88	2/min	Halothane	USP (24, p. 504)
Dichlorodi-fluoromethane	1.8 M × 2 mm I.D. 10% liquid G41/S1A (100–120 mesh)	Helium	150–280	4/min	None	NF (19, p. 2445)
	Stainless Steel, 1.8 M × 2 mm I.D. 1% G25/S12	Helium	70–170	10/min	None	NF (19, pp. 2445 and 2446)
Dichlorotetrafluoroethane						
Dicyclomine Hydrochloride capsules	Fused Silica 15 M × 0.5 mm coated with G3 (1 μm)	Nitrogen	160° – 240°	20°/min	Phenacetin	USP (24, pp. 549, 550 and 551)
Dicyclomine Hydrochloride injection						
Dicyclomine Hydrochloride syrup	30 M × 0.32 mm I.D. fused Silica column with G46(1 μm)	Helium	120–225	12/min	None	NF (19, p. 2447)
Dicyclomine Hydrochloride tablets	1.8 M × 4 mm I.D. 15% G39/S1A	Helium	160	FID	Dimethyl-formamide	USP (24, p. 580)
Dimethyl Glycol Monoethyl ether						
Dimethyl Sulfoxide gel						
Dimethyl Sulfoxide irrigation	Glass, 1.5 M × 3 mm I.D. 10% liquid phase G25 on packing S1A	Helium	100–170	10/min	Dibenzyl	USP (24, p. 581)

(Continued)

Table 2 Compendial applications of GC for the assay of pharmaceutical raw materials and dosage forms (Continued)

Material/dosage form	Column	Carrier gas	Temp. (°C)	Detector	Internal standard	Reference
Dimethyl Sulfoxide topical solution	1.8 M × 4 mm I.D. 10% liquid phase G16 on packing S1A	Helium	170	FID	Dimethyl-formamide	USP (24, p. 581)
Diphenoxylate Hydrochloride and Atropine Sulfate oral solution	Glass, 1.2 M × 4 mm I.D. 3% G3/S1 (for Atropine Sulfate)	Helium	230	FID	Homatropine Hydrobromide	USP (24, p. 585)
Enflurane	Stainless Steel, 3 M × 4 mm I.D. 20% G4/S1A (60–80 mesh)	Helium	60–125 6/min	TCD	None	USP (24, p. 642)
Conjugated Estrogens	15 M × 0.25 mm I.D. fused Silica capillary bonded with G19 (0.25 µm)	Hydrogen	220	FID	3-O-Methylsterone	USP (24, pp. 681, 682, 683 and 684)
Conjugated Estrogen tablets						
Esterified Estrogens						
Esterified Estrogen tablets						
Ethchlorvynol	Glass (pre-treated with 10% dimethyldi chlorosilane in toluene), 1.8 M × 4 mm I.D. 10% G16/S1AB (60–80 mesh)	Helium	160	TCD	None	USP (24, p. 691)
Ethchlorvynol capsules	Glass (pre-treated with 10% dimethyldi chlorosilane in toluene), 1.8 M × 4 mm I.D. 10% G16/S1AB (60–80 mesh)	Helium	160	FID	Chlorobutanol	USP (24, p. 691)
Eucalyptol	60 M × 0.32 mm I.D. Fused Silica capillary G16	Helium	60–200 6/min	FID	None	USP (24, p. 705)
Guaifenesin and Codeine Phosphate syrup	0.6 M × 2 mm I.D. 3% liquid G3/S1A (100–120 mesh) (For Codeine Phosphate)	Helium	210	FID	Hydrocodone Bitartrate	USP (24, p. 793)
Guaifenesin and Codeine Phosphate syrup	1.2 M × 4 mm I.D. 3% liquid G6/S1A (100–120 mesh) (For Guaifenesin)	Helium	170	FID	Dipropyl Phthalate	USP (24, p. 793)
Homosalate	30 M × 0.53 mm I.D. G27 (1 µm)	Hydrogen	70–220 6/min	FID	None	USP (24, p. 816)
Hydroxypropyl Methylcellulose	Glass, 1.8 M × 4 mm I.D. 20% G28/S1C (100–120 mesh)	Helium	130	TCD	Toluene	USP (24, p. 843)
Hyoscyamine tablets	Glass, 1.8 M × 2 mm I.D. 3% liquid G3/S1AB	Nitrogen	225	FID	Homatropine Hydrobromide	USP (24, p. 850)
Hyoscyamine Sulphate elixir	Glass, 1.8 M × 2 mm I.D. 3% liquid G3/S1AB	Nitrogen	225	FID	Hydrobromide	USP (24, pp. 851, 852 and 853)
Hyoscyamine Sulfate injection						
Hyoscyamine Sulphate oral solution						
Hyoscyamine Sulphate tablets						
Isobutane	Aluminum, 6 M × 3 mm I.D. 10% liquid G30 on nonacid washed S1C	Helium	33	TCD	None	NF (19, p. 2467)

(Continued)

Table 2 Compendial applications of GC for the assay of pharmaceutical raw materials and dosage forms (*Continued*)

Material/dosage form	Column	Carrier gas	Temp. (°C)	Detector	Internal standard	Reference
Isoamyl Methoxycinnamate	25 M × 0.32 mm I.D. coated G1 (0.1 μm)	Helium	60–240 8/min	FID	None	USP (24, p. 918)
Isoflurane	Nickel or Stainless Steel, 3.7 M × 2.4 mm I.D. 10% G31 + 15% G18 on S1C (60–80 mesh)	Helium	65–110 4/min	FID	Butyl Acetate	USP (24, p. 920)
Isoflurophate Ophthalmic solution	Glass, 1.8 M × 4 mm I.D. 5% G33/S1AB (80–100 mesh)	Helium	75–80	FID	Cyclohexanone	USP (24, pp. 921 and 922)
Isopropyl Alcohol	Stainless Steel, 1.8 M × 6.4 mm I.D. 10% liquid G20/S1A	Helium	55	TCD	None	USP (24, p. 927 and NF 19, p. 2468)
Isopropyl Myristate	1.8 M × 4 mm I.D. 10% liquid G8/S1 (100–120 mesh)	Nitrogen	90–210 2/min	FID	None	NF (19, p. 2468)
Isopropyl Palmitate	1.8 M × 4 mm I.D. 10% liquid G8/S1 (100–120 mesh)	Nitrogen	90–210 2/min	FID	None	NF (19, p. 2468)
Isosorbide	Glass, 0.6 M × 3 mm I.D. S9	Nitrogen	230	FID	Triethylene Glycol	USP (24, pp. 934 and 935)
Isosorbide oral solution						
Lindane cream	Glass, 1.8 M × 3 mm I.D. G3/S1A	Nitrogen	195	FID	n-Docosane	USP (24, pp. 976 and 977)
Lindane lotion						
Lindane shampoo						
Malathion lotion	Glass, 1.8 M × 2 mm I.D. 5% liquid G6/S1A (110–120 mesh)	Nitrogen	190	FID	Parathion	USP (24, p. 1012)
Menthol lozenges	30 M × 0.53 mm I.D. fused Silica coated with G16 (μm)	Helium	125	FID	Anethole in Hexanes	USP (24, p. 1038)
Menthyl Anthranilate	25 M × 0.32 mm I.D. Column coated with G1 (0.1 μm)	Helium	60–240 8/min	FID	None	USP (24, p. 1039)
Methadone Hydrochloride injection	Glass, 1.2 M × 4 mm I.D. 3% G2/S1A (10–20 mesh)	Helium	170	FID	Procaine	USP (24, p. 1057)
Methohexital Sodium for injection	1.2 M × 4 mm I.D. 3% G10/S1AB	Helium	230	FID	Aprobarbital	USP (24, p. 1069)
Methoxyflurane	Stainless Steel, 3 M × 4 mm I.D. G11/S1A	Helium	100–110	TCD	None	USP (24, p. 1074)
Methyl Alcohol	Stainless Steel, 2 M × 3 mm O.D. S4 (50–80 mesh)	Nitrogen	140	FID	None	NF (19, p. 2479)
Methyl Benzylidene Camphor	30 M × 0.32 mm I.D. fused Silica capillary coated with G1 (0.25 μm)	Helium	100–230 10/min	FID	None	USP (24, p. 1077)

(Continued)

Table 2 Compendial applications of GC for the assay of pharmaceutical raw materials and dosage forms (*Continued*)

Material/dosage form	Column	Carrier gas	Temp. (°C)	Detector	Internal standard	Reference
Methylcellulose	1.8 M × 4 mm I.D. 10% liquid G1/S1A (100–120 mesh)	Helium	100	FID	Toluene	USP (24, p. 1079)
Methylene Chloride	1.8 M × 4 mm I.D. 15% liquid G18/Unsilanized SIC (30–60 mesh)	Helium	60	TCD	None	NF (19, p. 2480)
Methylparaben, Ethylparaben, Propylparaben, Butylparaben	Glass or Stainless Steel, 1.8 M × 2 mm I.D. 5% G2/S1A	Helium or Nitrogen	150	FID	Benzophenone	USP (24, p. 1865)
Mibolerone oral solution	0.61 M × 3 mm I.D. 1% liquid G6/S1AB	Helium	175	FID	1,3,5-Triphenylbenzene	USP (24, p. 1112)
Miconazole Nitrate cream	1.2 M × 2 mm I.D. 3% G32/S1A	Helium	250	FID	Cholestane	USP (24, pp. 1114 and 1115)
Miconazole Nitrate topical powder						
Miconazole Nitrate vaginal suppositories						
Nitrogen Nitrogen 97 percent	3 M × 4 mm I.D. synthetic Alkali metal Aluminosilicate as a molecular sieve	Helium	Controlled	TCD	None	NF (19, p. 2485)
Octocrylene	60 M × 0.32 m I.D. column coated with G1 (0.25 µm)	Helium	80–280 4/min	FID	None	USP (24, p. 1213)
Octyldodecanol	2 M × 2 mm I.D. 3% G2/S1A	Nitrogen	80–300 6 min	FID	None	NF (19, p. 2286)
Octyl Methoxycinnamate	25 M × 0.32 mm I.D. column with G1	Helium	None	FID	Benzyl Benzoate	USP (24, p. 1213)
Octyl Salicylate	25 M × 0.32 mm I.D. column coated with G1 (0.1 µm)	Helium	60–240 8/min	FID	None	USP (24, p. 1214)
Oxandrolone tablets	Glass, 2 M × 4 mm I.D. 3% Methyl Silicone oil on 80- to 10- mesh acid-, base- and water-washed, flux calcined, silanized sliceaceous earth	Helium	250	FID	n-Octacosane	USP (24, p. 1225)
Penicillin G Procaine, Dihydrostreptomycin Sulfate, Chlorpheniramine Maleate, and Deamethasone injectable suspension (for Chlorpheniramine)	Glass, 1.8 M × 4 mm I.D. 1.2% G16 amd 0.5% KOH/S1A (10–120 mesh)	Nitrogen	180	FID	Brompheniramine Maleate	USP (24, p. 1281)
Pentobarbital elixir	Glass, 0.9 M × 4 mm I.D. 3 % liquid G10/S1A (80–10 mesh)	Nitrogen	190–210	FID	n-Tricosane	USP (24, p. 1293)
Pentobarbital Sodium capsules	Glass, 0.9 M × 4 mm I.D. 3 % liquid G10/S1A (80–10 mesh)	Nitrogen	190–210	FID	n-Tricosane	USP (24, p. 1295)
Perflubron	60 M × 0.25 mm I.D. G2 (1 µm)	Hydrogen	35–185 20/min	FID	None	USP (24, p. 1295)
Phendimetrazine Tartrate capsules	Glass, 1 M × 1 mm I.D. 3% G3/S1A	Helium	160	FID	Benzocaine	USP (p. 1055)

(Continued)

Table 2 Compendial applications of GC for the assay of pharmaceutical raw materials and dosage forms (*Continued*)

Material/dosage form	Column	Carrier gas	Temp. (°C)	Detector	Internal standard	Reference
Phendimetrazine Tartrate tablets	Glass, 1.2 M × 4 mm I.D. 10% liquid G3/S1AB	Helium	260	FID	Androsterone	USP (24, pp. 1392 and 1393)
Primidone oral suspension						
Primidone tablets						
Propane	Aluminum, 6 M × 3 mm I.D. 10% liquid G30 on non-acid washed S1C	Helium	33	TCD	None	NF (19, p. 2505)
Propoxyphene Hydrochloride, Aspirin and Caffeine capsules (for Propoxyphene and Caffeine)	0.6 M × 3 mm I.D. 3% Methyl Phenyl Silicone liquid/80–10 mesh siliceous earth	Nitrogen	175	FID	n-Tricosane	USP (24, p. 1423)
Propoxyphene Napsylate oral suspension	Glass or Stainless Steel, 0.6 M × 3 mm I.D. 3% G2/S1AB	Helium	160	FID	n-Tricosane	USP (24, p. 1425)
Propoxyphene Napsylate tablets						
Propoxyphene Napsylate and Aspirin tablets (for Propoxyphene)	1.2 M × 3 mm I.D. 3% G3/ S1A	Nitrogen	175	FID	n-Tricosane	USP (24, p. 1427)
Propylene Glycol	Glass or Stainless Steel, 1 M × 4 mm I.D. 5% G16/S5	Helium	122–200	TCD	None	USP (24, p. 1434)
Scopolamine Hydrobromide injection	Glass, 1.8 M × 2 mm I.D. 3% liquid G3/S1AB	Nitrogen	225	FID	Homatropine Hydrobromide	USP (24, pp. 1507, 1508 and 1509)
Scopolamine Hydrobromide ophthalmic solution						
Scopolamine Hydrobromide ophthalmic ointment						
Scopolamine Hydrobromide tablets						
Secobarbital elixir	Glass, 0.9 M × 4 mm I.D. 3% G10/S1A (80–100 mesh)	Nitrogen	200	FID	Butabarbital	USP (24, pp. 1509 and 1510)
Secobarbital Sodium capsules						
Secobarbital Sodium and Amobarbital	Glass, 0.6 M × 3.5 mm I.D. 3% liquid G10/S1AB (100–120 mesh)	Helium	175	FID	Aprobarbital	USP (24, p. 1511)
Sodium capsules						
Spectinomycin Hydrochloride	Glass, 0.6 M × 3 mm I.D. 5% G27/S1AB (80–100 mesh)	Helium	190	FID	Triphenyl-lantimony	USP (24, p. 1545)
Spectinomycin for injectable suspension	Glass, 0.6 M × 3 mm I.D. 5% G27/S1AB (80–100 mesh)	Helium	190	FID	Hexamethylsilazane	USP (24, p. 1545)
Stearic Acid	Glass, 1.5 M × 3 mm I.D. 15% G4/S1A	Helium	165	FID	None	NF (19, p. 2525)

(Continued)

Table 2 Compendial applications of GC for the assay of pharmaceutical raw materials and dosage forms (*Continued*)

Material/dosage form	Column	Carrier gas	Temp. (°C)	Detector	Internal standard	Reference
Purified Stearic Acid	2 M × 3 mm I.D. 10% G2/S1A	Helium	205	FID	None	NF (19, p. 2526)
Stearyl Alcohol						USP (24, pp. 1607 and 1608)
Terpin Hydrate	Glass, 1.2 M × 3.5 mm I.D. 6% G1/S1A	Nitrogen	120	FID	Biphenyl	
Terpin Hydrate elixir						
Terpin Hydrate and Codeine elixir	Glass, 1.2 M × 3.5 mm I.D. 6% G1/S1A	Nitrogen	230	FID	Biphenyl and N-Phenylcarbazole	USP (24, p. 1608)
Testosterone Cypionate	Glass, 1.2 M × 3 mm I.D. 1% G6/S1AB	Helium	260	FID	Cholesteryl Caprylate	USP (24, pp. 1610 and 1611)
Testosterone Cypionate injection						
Tetracaine and Menthol ointment	Glass, 1.8 M × 2 mm I.D. 10% G16/S1AB	Helium	170	FID	Decanol	USP (24, p. 1615)
Tiletamine and Zolazepam for injection	1.24 M × 4 mm I.D. 3% G2/S1AB (100–120 mesh)	Helium	150–230 10/min	FID	Tetraphenylethylene	USP (24, p. 1660)
Tocopherols excipient	Glass, 2 M × 4 mm I.D. 2–5% liquid G2/S1AB (80–1000 mesh)	Nitrogen	245–265	FID	Hexadecyl hexadecanoate	NF (19, p. 2531)
Tributyl Citrate	30 M × 0.32 mm I.D. G42 (0.5 µm)	Helium	80–225 20/min	FID	None	NF (19, p. 2532)
Trichloromono-fluormethane	Stainless Steel, 1.8 M × 2 mm I.D. 1% G25/S12	Helium	70–170 10/min	FID	None	NF (19, p. 2532)
Compound Undecylenic Acid ointment	Glass, 1.8 M × 2 mm I.D. 3% G1/S1A (100–20 mesh)	Helium	165	FID	Tridecanoic Acid	USP (24, p. 1729)
Valproic Acid	1.8 M × 2.0 mm I.D. 10% G34/S1A (80–100 mesh)	Helium	155	FID	Nonanoic Acid	USP (24, p. 1732)
Valproic Acid capsules	Glass, 1.8 M × 2 mm I.D. 10% G34/S1A (80–100 mesh)	Helium	150	FID	Biphenyl	USP (24, pp. 1733 and 1734)
Valproic Acid Syrup						
Vitamin E	Borosilicate glass, 2 M × 4 mm I.D. 2–5% liquid G2/S1AB 80–10 mesh	Nitrogen	245–265	FID	Hexadecyl Hexadecanoate	USP (24, pp. 1747 and 1749)
Vitamin E preparation						
Vitamin E capsules						
Vitamin E Polyethylene Glycol Succinate	5 M × 0.25 mm I.D. fused Silica capillary with G27 (0.25 µm)	Helium	260–340 20/min	FID	Ethyl Aracitate	NF (19, p. 2535)
Xylitol	30 M × 0.25 mm I.D. capillary with G46 (0.25 µm)	Helium	170°–215° 6/min 215–270 10/min	FID	Erythritol	NF (19, p. 2538)

Table 3 Compendial applications of GC for the chromatographic and radiochemical purity of pharmaceutical raw materials and dosage forms

Material/dosage form	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Alprazolam	Glass, 1.2 M × 3 mm I.D. 3% G6/S1AB	Helium	240	FID	None	USP (24, p. 64)
Amantadine Hydrochloride	Glass, 1.8 M × 2 mm I.D. G44/S1A (100–120 mesh)	None	100–200	FID	None	USP (24, p. 103)
Avobenzone	Fused Silica 25 M × 0.32 mm Capillary Coated with G1	Specified Helium	6/min 200–280 4/min	FID	None	USP (24, p. 181)
Chloroxylenol	Glass, 1.8 M × 4 mm I.D. 3% G16/S1A	Nitrogen	180	FID	None	USP (24, p. 391)
Clofibrate	15 M × 0.53 mm I.D. Capillary Coated with G1 (1.5 µm)	Helium	120–180 5/min	FID	None	USP (24, p. 442)
Dichlorodi-fluoromethane	Stainless Steel, 1.8 M × 2 mm I.D. 1% G25/S12	Helium	70–170 10/min	FID	None	NF (19, pp. 2445 and 2446)
Dichlorotetrafluoroethane	Glass (pre-treated with 10% dimethyldichlorosilane in toluene), 1.8 M × 4 mm I.D. 10% G16/S1AB (60–80 mesh)	Helium	160	TCD	None	USP (24, p. 691)
Ethchlorvynol	Glass, 1.8 M × 4 mm I.D. S11	Nitrogen	115–200 16/min	FID	None	NF (19, p. 2450)
Ethyl Acetate	30 M × 0.53 mm I.D. Fused Silica G43 (3 µm) with a 5 M × 0.53 mm I.D. Silica Guard Column (deactivated with phenylmethyl siloxane)	Helium	40–220 5/min	FID	None	USP (24, p. 780)
Glycerin	Stainless Steel, 3 M × 2 mm I.D. 20% G24/S1AB	Nitrogen	60	FID	1,1,2-Trichloro-1,2,2-trifluoroethane	USP (24, p. 806)
Haloethane					Decanol	USP (24, p. 1038) and NF (19, p. 2477)
Menthol	1.8 M × 2 mm I.D. 10% G16/S1AB	Helium	170	FID		

(Continued)

Table 3 Compendial applications of GC for the chromatographic and radiochemical purity of pharmaceutical raw materials and dosage forms (*Continued*)

Material/dosage form	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Meperidine Hydrochloride	Glass, 2 M × 2 mm I.D. 10% G3/S1A	Helium	190	FID	None	USP (24, p. 1039)
Mepivacaine Hydrochloride	Glass, 1.8 M × 4 mm I.D. 3% G19/S1A	Helium	230	FID	None	USP (24, p. 1041)
Nicotine	0.3 M × 0.53 mm I.D. fused Silica column bonded with G1 (1.5 μm)	Helium	50–250 5/min	FID	None	USP (24, p. 1179)
Octyl Methoxycinnamate	25 M × 0.32 mm I.D. Column with G1	Helium	80–300 Linearly	FID	None	USP (24, p. 1213)
Water O 15 Injection (radiochemical purity)	Stainless Steel, 1.8 M × 3 mm I.D. S3 (80–100 mesh)	Helium	150	TC and Radioactivity	None	USP (24, p. 1240)
Padimate O	Stainless Steel, 1.8 M × 3 mm I.D. 10% liquid G9/S1A	Helium	150–250 10/min	FID	None	USP (24, p. 1252)
Perflubron	60 M × 0.25 mm I.D. G2 (1 μm)	Hydrogen	35–185 20/min	FID	None	USP (24, p. 1295)
Squalane	1.8 M × 3 mm I.D. 3% G1/S1A	Nitrogen	130–270 6/min	FID	None	NF (19, p. 2524)
Triazolam	Glass, 1.2 M × 3 mm I.D. 3% G6/S1AB	Helium	240	FID	None	USP (24, p. 1695)
Trichloromono-fluoromethane	Stainless Steel, 1.8 M × 2 mm I.D. 1% G25/S12	Helium	70–170 10 min	FID	None	NF (19, p. 2532)
Triclosan	15 M × 0.53 mm I.D. capillary with G3	Helium	34	FID	None	USP (24, p. 1700)
Valproic Acid	60 M × 0.32 mm I.D. coated with G25	Helium	145	FID	None	USP (24, p. 1732)

Table 4 Compendial applications of GC for the identification of pharmaceutical raw materials and dosage forms

Material/dosage form	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Acetyltributyl Citrate	30 M × 0.32 mm I.D. column bonded with G42 (0.5 μm)	Helium	80–220 20/min	FID	None	NF (19, p. 2409)
Acetyltriethyl Citrate	1.5 M × 4 mm I.D. 3% G1/S1A	Nitrogen	250	FID	Squalane	USP (24, p. 121)
Amitraz						
Amitraz Concentrate for dip	2 M × 3 mm I.D. 10% liquid G2/S1	Helium	205	FID	None	NF (19, p. 2434)
Cetostearyl Alcohol	2 M × 3 mm I.D. 10% liquid G2/S1A	Helium	205	FID	None	NF (19, p. 2435)
Cetyl Alcohol	Glass, 1.83 M × 2 mm I.D. 3% G3/S1AB (80–100 mesh)	Helium	165	FID	Pyrene	USP (24, pp. 435, 436 and 437)
Clioquinol						
Clioquinol cream						
Clioquinol ointment						
Clioquinol and Hydrocortisone cream						
Clioquinol and Hydrocortisone ointment						
Colestipol Hydrochloride	Glass, 1.8 M × 3 mm I.D. 0.25% potassium hydroxide and 5% G16/S1A (80–100 mesh)	Helium	85	FID	None	USP (24, p. 465)
Dicyclomine Hydrochloride capsules	fused Silica 15 M × 0.5 mm coated with G3(1 μm)	Nitrogen	160–240 20/min	FID	Phenacetin	USP (24, pp. 549, 550 and 551)
Dicyclomine Hydrochloride injection						
Dicyclomine Hydrochloride syrup						
Dicyclomine Hydrochloride tablets						
Conjugated Estrogens	15 M × 0.25 mm I.D. fused Silica capillary bonded with G19 (0.25 μm)	Hydrogen	220	FID	3-O-Methylsterone	USP (24, pp. 681, 582, 683 and 684)
Conjugated Estrogen tablets						
Esterified Estrogens						
Esterified Estrogen tablets						
Glyceryl Behenate	1.8 M × 4 mm I.D. 10% liquid G27/S1A	Not specified	225	FID	None	NF (19, p. 2462)

(Continued)

Table 4 Compendial applications of GC for the identification of pharmaceutical raw materials and dosage forms (*Continued*)

Material/dosage form	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Guaifenesin and Codeine Phosphate syrup	0.6 M × 2 mm I.D. 3% liquid G3/S1A (100–120 mesh) (For Codeine Phosphate)	Helium	210	FID	Hydrocodone Bitartrate	USP (24, p. 793)
Guaifenesin and Codeine Phosphate syrup	1.2 M × 4 mm I.D. 37% liquid G6/S1A (100–120 mesh) (For Guaifenesin)	Helium	170	FID	Dipropyl Phthalate	USP (24, p. 793)
Hydrocortisone and Acetic Acid Otic solution	Glass, 1.8 M × 2 mm I.D. 20% liquid G35/S1A	Nitrogen	115–190 35/min	FID	Anisole	USP (24, p. 827)
Isosorbide oral solution	Glass, 0.6 M × 3 mm I.D. S9	Nitrogen	230	FID	Triethylene Glycol	USP (24, p. 935)
Perflubron	60 M × 0.25 mm I.D. G2 (1 μm)	Hydrogen	35–185 20/min	FID	None	USP (24, p. 1295)
Triclosan	15 M × 0.53 mm I.D. capillary with G3	Helium	34	FID	None	USP (24, p. 1700)
Valproic Acid	1.8 M × 2.0 mm I.D. 10% G34/S1A (80–100 mesh)	Helium	155	FID	Nonanoic Acid	USP (24, p. 1732)
Valproic Acid capsules	Glass, 1.8 M × 7 × 2 mm I.D. 10% G34/S1A (80–100 mesh)	Helium	150	FID	Biphenyl	USP (24, pp. 1733 and 1734)
Valproic Acid syrup	Glass, 2 M × 4 mm I.D. 2–5% liquid G2/S1AB (80–10 mesh)	Nitrogen	245–265	FID	Hexadecyl Hexadecanoate	USP (24, pp. 1747 and 1749)
Vitamin E Preparation	Glass, 2 M × 4 mm I.D. 2–5% liquid G2/S1AB (80–10 mesh)	Nitrogen	245–265	FID	Hexadecyl Hexadecanoate	USP (24, pp. 1747 and 1749)
Vitamin E capsules						
Vitamin E Polyethylene Glycol Succinate	15 M × 0.25 mm I.D. fused Silica capillary with G27 (0.25 μm)	Helium	260–340 20/min	FID	Ethyl Aracideate	NF (19, p. 25s35)

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Amoxicillin	Dimethylaniline	2 M X 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP (24, p. 129)
Ampicillin	Dimethylaniline	2 M X 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP (24, p. 136)
Ampicillin Sodium	Dimethylaniline	2 M X 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FIDN	N-Diethylaniline	USP (24, p. 140)
Ampicillin Sodium	Methylene Chloride	glass, 1.8 M X 4 mm I.D. 10% 39/S1A	Nitrogen	65	FID	Dioxane	USP (24, p. 140)
Amyl Nitrite	Total Nitrites	2 M X 3 mm I.D. 25% methyl polysiloxane on suitable calcined diatomate	Helium	80	TCD	None	USP (24, pp. 144 and 145)
Amyl Nitrite inhalant							
Bacampicillin	Dimethylaniline	2 M X 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP (24, p. 189)
Hydrochloride Benzethonium	Acetone and Alcohol	1.2 M X 4 mm S3 (80–100 mesh)	Helium	120	FID	Methanol	USP (24, p. 204)
Chloride Tincture Brompheniramine	Related substances	Glass, 1.2 M X 4 mm I.D. 3% G3/S1AB	Helium	190	FID	None	USP (24, p. 251)
Maleate Bupivacaine	Residual solvents	2 M X 6 mm I.D. S3	Nitrogen	175	FID	None	USP (24, p. 256)
Hydrochloride Butyl Alcohol	Butyl Ether	Stainless steel, 2 M X 6 mm I.D. 25% liquid G29 3,3' thiodipropionitrile/SIC (30–40 mesh)	Helium	85	TCD	None	NF (19, p. 2422)
Carbomer 910	Benzene	30 M X 0.53 mm I.D. fused Silica analytical column with G34 (3.0 µm) and a 5 M X 0.53 mm I.D. guard column deactivated with Phenylmethyl Siloxane	Helium	40 – 260 50/min	FID	None	NF (19, pp. 2426, 2427 and 2428)

(Continued)

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms (*Continued*)

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Carbomer 934							
Carbomer 934P							
Carbomer 940							
Carbomer 941							
Carbomer 1342							
Cefadroxil	Dimethylaniline	2 M × 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP (24, p. 326)
Cefoxitin Sodium	Acetone and Methanol	Glass, 1.8 M × 6.3 mm I.D. S2, silane treated 60–80 mesh glass beads precolumn	Nitrogen	110	FID	None	USP (24, p. 345)
Cephalexin	Dimethylaniline	2 M × 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP (24, p. 361)
Cephalexin Hydrochloride							
Maleate	Related substances	Glass, 1.2 M × 4 mm I.D. 3% G3/S1AB	Helium	190	FID	None	USP (24, p. 392)
Maleate							
Ciclopirox Oxamine	Benzyl Alcohol	Glass, 2 M × 4 mm I.D. 3% G3/S1AB(100–120 mesh)	Nitrogen	100	FID	1-Nonyl Alcohol	USP (24, pp. 410 and 411)
Cream							
Ciclopirox Oxamine Topical suspension							
Cilastatin Sodium	Acetone, Methanol and Mesityl Oxide	30 M × 0.53 mm capillary, G16 1 μ film	Helium	50–70 8/min	FID	n-Propyl Alcohol	USP (24, p. 411)
Clavulanate	Methanol and tert-butylamine	30 M × 0.32 mm capillary, G1	Nitrogen	40 – 200 55/min	FID	None	USP (24, p. 426)
Potassium Clofibrate	p-chlorophenol	15 M × 0.53 mm I.D. capillary coated with G1 (1.5 m)	Helium	120 – 180 5/min	FID	None	USP (24, p. 442)
Cloxacillin Sodium	Dimethylaniline	2 M × 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP (24, p. 456)
Colchicine	Residual Chloroform and Ethyl Acetate	Glass or Stainless Steel, 1.5 M × 4 mm I.D. 20% G14/S1	Nitrogen	75	FID	n-Propanol	USP (24, p. 464)

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms (*Continued*)

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Collodion	Alcohol	Glass, 1.8 M × 3.5 mm I.D. S3	Helium	150	TCD	1,2-Dichloroethane	USP (24,P. 469)
Flexible collodion							
Cyclosporine injection	Alcohol	Glass, 2 M × 2 mm I.D. S3	Nitrogen	145–270 32/min	FID	n-Propyl Alcohol	USP (24, pp. 488 and 489)
Cyclosporine oral solution							
Cyclosporine injection Cyclosporine oral solution	Alcohol	Glass, 2 M × 2 mm I.D. S3	Nitrogen	145–270 32/min	FID	n-Propyl Alcohol	USP (24, pp. 488 and 489)
Desflurane	Related compounds and Trichlorofluoromethane, Dichlorofluoromethane, Methylene Chloride, Chloroform, Trichlorotrifluoroethane and Isoflurane	Stainless Steel, 6.1 M × 2.4 mm I.D. 25% G16/S1A (80–100 mesh)	Helium	75	FID	None	USP (24, p. 504)
Dexbrom-pheniramine Maleate	Related substances	Glass, 1.2 M × 4 mm I.D. 3% G3/S1AB	Helium	190	FID	None	USP (24, p. 520)
Maleate	Related substances	Glass, 1.2 M × 4 mm I.D. 3% G3/S1AB	Helium	190	FID	None	USP (24, p. 520)
Dexpanthenol	Pantolactone	1.8 M × 2 mm I.D. 5% G2/S1A	Helium or Nitrogen	170	FID	2,6-Dimethylphenol	USP (24, p. 523)
Preparation							
Dextran 40 Dextran 70	Alcohol and related impurities	1.8 M × 2 mm I.D. S3	Nitrogen	160	FID	None	USP (24, pp. 523 and 526)
Dextran 70							
Dicloxacillin Sodium	Dimethylaniline	2 M × 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP (24, p. 548)
Diethylene Glycol Monoethyl Ether	Ethylene Oxide	Glass or Quartz, 30 M × 0.32 mm I.D. capillary with G1 (1.0 µm)	Helium	50 – 180 5/min 180–230 30/min	FID	None	NF (19, p. 2447)

(Continued)

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms (*Continued*)

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Diethylene Glycol	Ethylene Oxide	Glass or Quartz, 30 M × 0.32 mm I.D. capillary with G1 (1.0 μm)	Helium	50 – 180 5/min 180–230 30/min	FID	None	NF (19, p. 2447)
Monoethyl Ether Dihydroxyaluminum Sodium Carbonate Dimethyl	Isopropyl Alcohol	0.9 M × 3 mm I.D. S3		180	FID	None	USP (24, p. 572)
	Dimethyl Sulfone	1.5 M × 3 mm I.D. 10% liquid phase G25/ S1A	Helium	100–170 10/min	FID	Dibenzyl	USP (24, p. 579 and USP 24-NF 19 First Suppt, p. 2608)
Sulfoxide Doxylamine Succinate	Secondary peaks	2 M × 4 mm I.D. 5%G16, 5% G12/S1A (60–80 mesh)	Helium	212	FID	None	USP (24, p. 612)
Dyphylline elixir Dyphylline and Guaifenesin elixir Conjugated Estrogens	Alcohol	Glass, 0.75 M × 4 mm I.D. 20% G20/S1AB	Nitrogen	85	FID	None	USP (24, pp. 618 and 619)
	Estrone, Equilin and 17α-dihydroequilin (free steroids)	15 M × 0.25 mm I.D. fused Silica capillary bonded with G19(0.25 μm)	Hydrogen	220	FID	3-O-Methylestrone	USP (24, pp. 681 and 683)
Esterified Estrogens Ether	Low-boiling hydrocarbons	Stainless Steel, 3.7 M × 2 mm I.D 30%G22/S1C (30–60 mesh)	Nitrogen	80	FID	None	USP (24, p. 692)
Ethosuximide	2-Ethyl-2-methylsuccinic Anhydride and other impurities	1.8 M × 6.4 mm I.D. 5% G5/ S1A (60–80 mesh)	Helium	140	HFD	None	USP (24, p. 695)
Etodolac	Alcohol and Methanol	25 M × 0.32 mm I.D. fused Silica capillary G36 (5 μm)	Helium	45–280 30/min	FID	Isopropyl Alcohol	USP 244, p. 701)

(Continued)

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms (*Continued*)

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Fluocinonide topical solution	Alcohol content	Glass, 1.8 M × 2 mm I.D. S3 (80–120 mesh)	Nitrogen or Helium	130	FID	Isopropyl Alcohol	USP (24, p. 729)
Gadodiamide	Acetone, Ethyl Alcohol, Isopropyl Alcohol	30 M × 0.32 mm I.D. capillary with G43 (1.8 µm)	Helium	40	FID	Methyl Ethyl Ketone	USP (24 - NF 19 First Suppl.P. 2618)
Gentamicin Sulfate	Methanol	1.5 M × 4 mm I.D. S3	Nitrogen	120 – 140	FID	n-Propyl Alcohol	USP (24, p. 765)
Glycerin	Methylene Chloride, Benzene, Trichloroethylene, 1,4-Dioxane, Chloroform, Heuylene Glycol	30 M × 0.53 mm I.D. fused Silica G43 (3 µm) with a 5 M × 0.53 mm I.D. Sillica guard column (deactivated with phenylmethyl siloxane)	Helium	40–220 5/mm	FID	None	USP (24, p. 780 and NF 19, p. 2461)
Glycerol	Free Glycerin	Glass, 2.4 M × 4 mm I.D. 2% liquid G16/S1A (80–100 mesh)	Helium	190 – 200	FID	Tributyrin	NF (19, p. 2463)
Monostearate Glycerol	Monoglycerides	Glass, 2.4 M × 4 mm I.D. 2% liquid G27/S1A (80–100 mesh)	Helium	270 – 280	FID	Hexadecyl Hexadecanoate	NF (19, p. 2463)
Monostearate	Alcohol content	1.8 M × 2 mm I.D. 5% liquid G16/S1A (100–120 mesh)	Helium	50–100 20/min	FID	Acetone	USP (24, p. 793)
Guaifenesin and Codeine Phosphate syrup	2,6-dichlorobenzaldehyde	Glass, 1.8 M × 3 mm I.D. 20% G1/S1A (80–100 mesh)	Nitrogen	190	FID	p-Chlorobenzaldehyde	USP (24, p. 796)
Guanabenz Acetate	2,3,7,8-tetrachlorodibenzo-p-dioxin	Glass, 1 M × 2 mm I.D. G1/S1	Helium	250	Mass Spectrograph	None	USP (24, p. 810)
Hexachlorophene	Acetic Acid	Glass, 1.8 M × 2 mm I.D. 20% liquid G35/S1A	Nitrogen	115–190 35/min	FID	Anisole	USP (24, p. 827)

(Continued)

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms (*Continued*)

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Ifosfamide	2-chloroethylamine hydrochloride	1.8 M × 2 mm I.D. 10% liquid G16, 2% KOH/S1A (80–100 mesh)	Nitrogen	140°	FID	None	USP (24, p. 861)
Imipenem	Acetone, Isopropyl Alcohol	1.8 M × 3 mm I.D. 10% G16/S5	Helium	70–170 32/min	FID	n-Propyl Alcohol	USP (24, p. 863)
Indomethacin	Acetone	Glass, 1.8 M × 3 mm I.D. S3	Nitrogen	165	FID	None	USP (24, p. 878)
Sodium Iohexol	Methanol, Isopropyl Alcohol, Methoxyethanol	Glass, 2 M × 2 mm I.D. S6	Nitrogen	125–225 Maximum Rate	FID	None	USP (24, p. 900)
Iopromide	Alcohol (limit)	30 M × 0.25 mm I.D. capillary coated liquid G43 (1.4 µm)	Helium	40–70 5/min 70–220 30/min	FID	None	USP (24, p. 904)
Ioxilan	Residual Methanol	10 M × 0.53 mm I.D. fused Silica capillary/S2	Helium	45–80 5/min	FID	Dehydrated Alcohol	USP (24, p. 911 and 912)
Ioxilan injection Iron dextran injection	Phenol (limit)	1.2 M × 3 mm I.D. 5% G16/S1A	Helium or Nitrogen	145	FID	Benzyl Alcohol	USP (24, p. 916)
Isoflurane	Acetone, 1-chloro-2,2,2-trifluoroethyl-chlorodifluoro-methyl ether 2,2,2-trifluoroethyl-difluoro-methyl ether	Nickel or Stainless Steel, 3.7 M × 2.4 mm I.D. 10% G31 + 15% G18 on S1C (60–80–mesh)	Helium	65–110 4/min	FID	Butyl Acetate	USP 24, p. 920
Azeotropic Isopropyl Alcohol	Air, Diethyl Ether, Diisopropyl Ether, Acetone, Isopropyl Alcohol, 2-Butanol, n-Propyl Alcohol, Water	Stainless Steel, 1.8 M × 6.4 mm I.D. 10% liquid G20/S1A	Helium	55	FID	None	USP 24, p. 927
Isosorbide	Methyl-ethyl Ketone	Glass or Stainless Steel, 0.6 M × 2 mm I.D. 25% G16 On Unsilanized S1A	Nitrogen	70	FID	Methyl-isobutyl Ketone	USP 24, p. 934
Isoxsuprine	Related compounds	Glass, 2 M × 3 mm I.D. 3% liquid G3/S1A	Nitrogen	215	FID	None	USP 24, p. 940

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms (*Continued*)

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Polycarbophil	Ethyl Acetate	10 ft × 2 mm I.D. 1% G25/S12	Helium	160	FID	Methyl Ethyl Ketone	USP 24, p. 1348
Poloxamer	Limit of Free Ethylene Oxide Propylene Oxide, 1,4 dioxane	50 M × 0.32 mm I.D. fused Silica with G27 (5 μm)	Helium	70–240 10/min	FID	None	NF 19, p. 2492 and USP 24-NF 19 First Suppt.P. 2725
Polyethylene Glycol	Limit of Free Ethylene Oxide and 1,4 dioxane	50 M × 0.32 mm I.D. fused Silica with G27 (5 μm)	Helium	70–250 10/min	FID	None	NF 19, p. 2493 and USP 24-NF 19 First Suppt.P. 2726
Polyethylene Glycol	Ethylene Glycol and Diethylene Glycol	Stainless Steel, 1.5 M × 3 mm I.D. 12% G13/SINS	Nitrogen	165	FID	None	NF 19, p. 2493
Polyethylene Glycol Monomethyl Ether	Ethylene Oxide and 1,4 dioxane	50 M × 0.32 mm I.D. fused Silica with G27 (5 xμm)	Helium	70 – 250 10/min	FID	None	NF 19, p. 2495
Polyethylene Glycol Monomethyl Ether	Ethylene Glycol and Diethylene Glycol	1M × 3mm I.D. S2 (60–80 mesh)	Nitrogen	200	FID	None	NF 19, p. 2495
Polyethylene Glycol Monomethyl Ether	2-methoxyethanol	15 M × 0.53 mm I.D. fused Silica capillary column with G16 (1 μm)	Helium	70–250 10/min	FID	None	NF 19, p. 2495
Polyethylene Oxide	Free Ethylene Oxide	10 M × 0.53 mm I.D. Capillary Column with G45 (20 μm)	Helium	70–200 10/min	FID	None	NF 19, p. 2497
Polyoxyl 10 Oleyl Ether	Free Ethylene Oxide	Stainless Steel, 1.8 M × 3 mm I.D. (OD) S3	Helium	160	FID	n-Butyl Chloride	NF 19, p. 2498
Polyoxyl 20 Cetostearyl Ether	Free Ethylene Oxide	Stainless Steel, 1.8 M × 3 mm I.D. (OD) S3	Helium	160	FID	n-Butyl Chloride	NF 19, p. 2499
Procyclidine Hydrochloride	Related compounds	Glass 1 M × 2 mm I.D. 10% PEG 20,000 and 2% KOH/SIA	Helium	180	FID	None	USP 24, p. 1406
Propafenone Hydrochloride	Methanol, Acetone	30 M × 0.53 mm I.D. fused Silica column with G43 (3 μm) and a 5 M × 0.53 mm I.D. Silica guard column deactivated with Phenylmethyl Siloxane	Helium	40–240 Rapidly	FID	None	USP 24, p. 1414

Table 5 Compendial applications of GC for the presence of volatile matter, intermediates, and related substances in raw materials and dosage forms (*Continued*)

Material/dosage forms	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Sufentanil Citrate	Acetone	Glass, 1.83 M × 4 mm I.D. S2	Nitrogen	175	FID	None	USP 24 - NF 19 First Suppl, p. 2658
Tamoxifen Citrate	Related impurities	Glass, 1 M × 4 mm I.D. 5% liquid G17/S1AB (100–120 mesh)	Helium	260	FID	None	USP 24, p. 1586
Ticarcillin Disodium Ticarcillin injection	Dimethylaniline	2 M × 2 mm I.D. 3% G3/silanized S1A	Nitrogen	120	FID	Napthalene	USP 24, p. 1657 and 1659
Propylene Glycol	Propylene Glycol	15 M × 0.53 mm I.D. fused Silica with liquid G16 (1 µm)	Helium	100	FID	Pentadecane	USP 24, p. 1662
Triclosan	Related compounds	15 M × 0.53 mm I.D. capillary with G3	Helium	34	FID	None	USP 24, p. 1700
Triclosan	2,3,7,8-tetrachlorodibenzo-p-dioxin, 2,3,7,8-tetrachlorodibenzofuran	30 M × 0.53 mm I.D. capillary with G3	Helium	80–180 20/min 180–270 4/min	Mass Spec with electron impact ionization	C Tetrachloro-dibenzo-p-13 labelled 2,3,7,8-dioxin, C13 Labelled 2,3,7,8-Tetrachloro-dibenzofuran	USP 24, p. 1700
Warfarin Sodium	Isopropyl Alcohol	Glass, 1.8 M × 4 mm I.D. S2 (80–100 mesh)	Nitrogen	140	FID	n-Propyl Alcohol	USP 24, p. 1750
Xanthan gum	Isopropyl Alcohol	Stainless Steel, 1.8 M × 3.2 mm I.D. silanized S3 (80–100 mesh)	Helium	165	FID	Tertiary Butyl Alcohol	NF 19, p. 2537
Xylazine	Acetone, Isopropyl Alcohol	1.8 M × 2mm I.D. 0.1% G25/ S7 (80–10 mesh)	Helium	30–100 10/min 100–220 15/min	FID	None	USP 24, p. 1756
Xylitol	Other Polyols	30 M × 0.25 mm I.D. capillary with G 46 (0.25 µm)	Helium	170–215 6/min 215–270 10/min	FID	Erythritol	NF 19, p.2538

Table 6 Compendial applications of GC for the determination of water in pharmaceutical raw materials and dosage forms

Material/dosage form	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Acetone	Stainless Steel, 1.5 <i>M</i> × 6 mm I.D. S4	Helium	180	TCD	None	NF (19, p. 2409)
Echothiophate Iodide for Ophthalmic Solution	Glass, 1.8 <i>M</i> × 2 mm I.D. silanised S3 (80–100 mesh)	Helium	115	TCD	Anhydrous Methanol	USP (24, p. 621)
Gonadorelin Hydrochloride	Glass, 1.8 <i>M</i> × 2 mm I.D. S3 (80–100 mesh)	Helium	100	TCD	Anhydrous Methanol	USP (24, p. 784)

Table 7 Compendial applications of GC for the presence of isomers, isomeric purity, and racemate ratios in pharmaceutical raw materials

Material	Analyte	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Butorphanol Tartrate	Purity and presence of α -isomer	Glass, 1.8 <i>M</i> × 4 mm I.D. 3% G3/S1	Nitrogen	250	FID	None	USP (24,p.271)
Ethchlorvynol	E-Ethchlorvynol	Glass (pretreated with 10% dimethyldichlorosilane in toluene), 1.8 <i>M</i> × 4 mm I.D. 10% G16/S1AB (60–80 mesh)	Helium	160	TCD	None	USP (24, p. 691)
Fludeoxyglucose F 18 injection	Isomeric purity	1.8 <i>M</i> × 3 mm I.D. 4% G2 (SF-30),6% G6 (OV 210)/S1A (80–100 mesh) (Chromosorb W-HP)	Helium	150	FID	None	USP (24, p. 733)
Labetalol Hydrochloride	Racemate ratio	Glass, 1.8 <i>M</i> times; 2 mm I.D. 10% G3/S1AB (10–120 mesh)	Nitrogen	320	FID	None	USP (24, p. 949)
Anhydrous Lactose	Content of alpha and beta anomers	Glass, 0.9 <i>M</i> × 4 mm I.D. 3% liquid G19/S1A	Helium	215	FID	None	NF (19, p. 2470)
Phendimetrazine Tartrate	L-erythro isomer	25 <i>M</i> × 0.25 mm I.D. capillary column G1 (0.4 μ m)	Helium	140	FID	None	USP (24, p. 1301)

Table 8 Compendial applications of GC for the determination of alcohol content in raw materials and dosage forms^a

Dosage form	Reference
Acetaminophen oral solution	USP (24, p. 18)
Oral solution containing at least three of the following—Acetaminophen and salts of Chlorpheniramine, Dextromethorphan, and Phenylpropanolamine	USP (24, p. 24)
Oral solution containing at least three of the following—Acetaminophen and salts of Chlorpheniramine, Dextromethorphan, and Pseudoephedrine	USP (24, p. 31)
Acetaminophen and Codeine Phosphate oral solution	USP (24, p. 35)
Acetaminophen, Dextromethorphan, Hydrobromide, Doxylamine Succinate, and Pseudoephedrine Hydrochloride oral solution	USP (24, p. 37)
Aminobenzoic Acid gel and topical solution	USP (24, p. 110 and, p. 111)
Aromatic elixir	NF (p. 1901)
Belladonna tincture	USP (24, p. 201) ^b
Compound Benzoin tincture	USP (24, p. 211)
Butabarbital Sodium elixir	USP (24, p. 262)
Camphor spirit	USP (24, p. 293)
Aromatic Cascara fluid extract	USP (24, p. 322)
Aromatic elixir	NF (19, p. 2415)
Cinoxate Lotion	USP (24, p. 416)
Desoximetasone gel	USP (24, p. 508) ^c
Dexamethasone elixir	USP (24, p. 512)
Dexamethasone Sodium Phosphate	USP (24, p. 516) ^d
Dexamethasone Sodium Phosphate inhalation aerosol	USP (24, p. 517)
Ergoloid Mesylates oral solution	USP (24, p. 656)
Erythromycin topical solution	USP (24, p. 667)
Etoposide injection	USP (24, p. 704)
Green Soap tincture	USP (24, p. 788)
Isoetharine Mesylate inhalation aerosol	USP (24, p. 919)
Isoproterenol Hydrochloride inhalation	USP (24, p. 928) ^d
Methdilazine Hydrochloride syrup	USP (24, p. 1061)
Methylcellulose oral solution	USP (24, p. 1080)
Nitroglycerin injection	USP (24, p. 1190)
Nortriptyline Hydrochloride oral solution	USP (24, p. 1206)
Opium tincture	USP (24, p. 1221)
Oxycodone Hydrochloride oral solution	USP (24, p. 1234) ^b
Paregoric	USP (24, p. 1263)
Peppermint spirit	USP (24, p. 1295)
Phenobarbital elixir	USP (24, p. 1306)
Potassium Chloride oral solution	USP (24, p. 1358) ^b
Potassium Gluconate elixir	USP (24, p. 1365)
Prednisilone syrup	USP (24, p. 1381)
Prednisone oral solution	USP (24, p. 1388)
Prednisone syrup	USP (24, p. 1389)
Propoxyphene Napsylate oral suspension	USP (24, p. 1425)
Pseudoephedrine Hydrochloride, Carbinoxamine Maleate, and Dextromethorphan Hydrobromide oral solution	USP (24) NF 19 First Suppl, p. 2654)
Resorcinol and Sulfur lotion	USP (24, p. 1478)
Sulfamethoxazole and Trimethoprim oral suspension	USP (24, p. 1573)
Terpin Hydrate elixir Terpin Hydrate and Codeine elixir	USP (24, pp. 1607 and 1608)
Theophylline and Guaifenesin oral solution	USP (24, p. 1634) ^b
Theophylline Sodium Glycinate elixir	USP (24, p. 1635)
Thiamine Hydrochloride elixir	USP (24, p. 1639) ^b
Thiamine Mononitrate elixir	USP (24, p. 1641) ^b

Table 11 Miscellaneous compendial applications of GC for pharmaceutical raw materials and dosage forms

Material/dosage form	Column	Carrier gas	Temp (°C)	Detector	Internal standard	Reference
Cocoa butter (fatty acid composition)	15 M × 0.25 mm fused Silica capillary with G 19 (0.25 μm)	Helium	180–240 10/min	FID	None	NF (19, p. 2438)
Corn oil (fatty acid composition)	Glass, 1.8 M × 4 mm I.D. 10% liquid G 4/S1A	Nitrogen	175	FID	None	NF (19, p. 2439)
Dexchlorpheniramine Maleate tablets (dissolution rate)	1.8 M × 2 mm I.D. 1.2% G16, 0.5% KOH/S1AB	Helium	205	FID	Dexbrom-pheniramine Maleate	USP (24, p. 522)
Fatty acid composition	30 M × 0.53 mm I.D. Fused Silica with G16 (1 μm)	Helium	70–260 5/min	FID	None	USP (24, p. 1871)
Mecamylamine Hydrochloride tablets (dissolution rate)	30 M × 0.53 mm I.D. capillary coated with G 27 (1–5 μm)	Helium	150	FID	Biphenyl	USP (24, p. 1023)
Organophosphorous insecticides (See Table 5 USP (24 Page 1890))	30 M × 0.53 mm I.D. fused Silica with G1 (0.25 μm)	Hydrogen, Helium or Nitrogen	80–150 30 /min 150– 280 4/min	Alkali Fid or FPD	None	USP (24, p. 1889)
Organochlorine and Pyrethroid insecticides (See Table 6 USP 24 Page 1890)	30 M × 0.32 mm I.D. fused Silica with G1 (0.25 μm)	Hydrogen, Helium or Nitrogen	80–150 30/min 150– 280 4/min	ECD	None	USP (24, p. 1890)
Saw Palmetto (fatty acid content) Powdered Saw Palmetto (fatty acid content)	30 M × 0.25 mm I.D. fused Silica capillary with G16(0.25 μm)	Helium	120–220 50/min	FID	Nonadecane	NF 19, pp. 2510 and 2512)
Safflower oil (fatty acid composition)	Glass, 1.5 M × 4 mm I.D. 10% liquid G4/S1A	Nitrogen	175	FID	None	USP (24, p. 1499)
Soybean Oil (fatty acid composition)	Glass, 1.5 M × 4 mm I.D. 10% liquid G4/S1A	Nitrogen	175	FID	None	USP (24, p. 1544 and NF 19, p. 2524)

USP 24 NF-19 2000 (21)**Phases**

G1	Dimethylpolysiloxane oil	G14	Polyethylene glycol (average molecular weight of 950–1050)
G2	Dimethylpolysiloxane gum	G15	Polyethylene glycol (average molecular weight of 3000–3700)
G3	50% Phenyl-50% methylpolysiloxane	G16	Polyethylene glycol compound (average molecular weight about 15,000). A high-molecular-weight compound of polyethylene glycol with a diepoxide linker. Available commercially as polyethylene glycol compound 20M, or as Carbowax 20M, from suppliers of chromatographic reagents.
G4	Diethylene glycol succinate polyester		
G5	3-Cyanopropylpolysiloxane		
G6	Trifluoropropylmethylpolysiloxane		
G7	50% 3-Cyanopropyl-50% phenylmethylsilicone		
G8	90% 3-Cyanopropyl-10% phenylmethylsilicone		
G9	Methylvinylpolysiloxane	G17	75% Phenyl-25% methylpolysiloxane
G10	Polyamide formed by reacting a C ₃₆ dicarboxylic acid with 1,3-di-4-piperdylpropane and piperidine in the respective mole ratios of 1.00:0.90:0.20	G18	Polyalkylene glycol
		G19	25% Phenyl–25% cyanopropyl-50% methylsilicone
G11	Bis(2-ethylhexyl) sebacate polyester	G20	Polyethylene glycol (average molecular weight of 380–420)
G12	Phenyldiethanolamine succinate polyester		
G13	Sorbitol	G21	Neopentyl glycol succinate

- G22 Bis(2-ethylhexyl) phthalate
 G23 Polyethylene glycol adipate
 G24 Diisodecyl phthalate
 G25 Polyethylene glycol compound TPA. A high-molecular-weight compound of a polyethylene glycol and a diepoxide that is esterified with terephthalic acid. Available commercially as Carbowax 20M-TPA from suppliers of chromatographic reagents.
 G26 25% 2-Cyanoethyl-75% methylpolysiloxane
 G27 5% Phenyl-95% methylpolysiloxane
 G28 25% Phenyl-75% methylpolysiloxane
 G29 3-3'-Thiodipropionitrile
 G30 Tetraethylene glycol dimethyl ether
 G31 Nonylphenoxypoly(ethyleneoxy)ethanol (average ethyleneoxy chain length is 30); Nonoxynol 30
 G32 20% Phenylmethyl-80% dimethylpolysiloxane
 G33 20% Carborane-80% methylsilicone
 G34 Diethylene glycol succinate polyester stabilized with phosphoric acid
 G35 A high molecular weight compound of a polyethylene glycol and a diepoxide that is esterified with nitroterephthalic acid
 G36 1% Vinyl-5% phenylmethylpolysiloxane
 G37 Polyimide
 G38 Phase G1 containing a small percentage of tailing inhibitor (Commercially available as SP2100/0.1% Carbowax 1500 from Supelco)
 G39 Polyethylene glycol (average molecular weight about 1500)
 G40 Ethylene glycol adipate
 G41 Phenylmethyldimethylsilicone (10% phenyl-substituted)
 G42 35% phenyl-65% dimethylpolysiloxane (percentages refer to molar substitution)
 G43 6% cyanopropylphenyl-94% dimethylpolysiloxane (percentages refer to molar substitution)
 G44 2% low-molecular-weight petrolatum hydrocarbon grease and 1% solution of potassium hydroxide
 G45 Divinylbenzene-ethylene glycol-dimethylacrylate
 G46 14% cyanopropylphenol-86% methylpolysiloxane

Supports USP 24 NF-19 2000 (21) (NOTE:
Unless otherwise specified, mesh sizes of 80–100 or, alternatively, 100–120 are intended.)

- S1A Siliceous earth for gas chromatography has been flux calcined by mixing diatomite with Na_2CO_3

flux and calcining above 900° . The siliceous earth is acid-washed, then water-washed until neutral, but not base-washed. The siliceous earth may be silanized by treating with an agent such as dimethyldichlorosilane (unless otherwise specified in the individual monograph, silanized support is intended) to mask surface silanol groups.

- S1AB The siliceous earth as described above is both acid- and base-washed (unless otherwise specified in the individual monograph, silanized support is intended).
 S1C A support prepared from crushed firebrick and calcined or burned with a clay binder above 900° with subsequent acid-wash. It may be silanized.
 S1NS The siliceous earth is untreated.
 S2 Styrene-divinylbenzene copolymer having a nominal surface area of less than 50 m^2 per g and an average pore diameter of $0.3\text{--}0.4 \mu\text{m}$.
 S3 Copolymer of ethylvinylbenzene and divinylbenzene, having a nominal surface area of $500\text{--}600 \text{ m}^2/\text{g}$ and an average pore diameter of $0.0075 \mu\text{m}$.
 S4 styrene-divinylbenzene copolymer with aromatic -O and -N groups, having a nominal surface area of $400\text{--}600 \text{ m}^2/\text{g}$ and an average pore diameter of $0.0076 \mu\text{m}$.
 S5 40- to 60 mesh, high molecular weight tetrafluorethylene polymer.
 S6 Styrene-divinylbenzene copolymer, having a nominal surface area of $250\text{--}350 \text{ m}^2/\text{g}$ and an average pore diameter of $0.0091 \mu\text{m}$.
 S7 Graphitized carbon having a nominal surface area of $12 \text{ m}^2/\text{g}$.
 S8 Copolymer of 4-vinyl-pyridine and styrene-divinylbenzene.
 S9 A porous polymer based on 2,6-diphenyl-p-phenylene oxide.
 S10 A highly polar cross-linked copolymer of acrylonitrile and divinylbenzene.
 S11 Graphitized carbon having a nominal surface area of $9 \text{ m}^2/\text{g}$ modified with small amounts of petrolatum and polyethylene glycol compound (commercially available as SP1500 on Carbopack B from Supelco).
 S12 Graphitized carbon having a nominal surface area of $100 \text{ m}^2/\text{g}$.

Biological Fluids

While it is clearly apparent that packed columns are mainly used for the various compendial tests, the use of capillary columns for the determination of therapeutic agents in biological fluids has become increasingly

popular. The high resolution capability of capillary columns often overcomes the problems of interference from the biological sample matrix and, coupled with specificity and increased sensitivity has made possible the quantitative analysis of many, formerly undeterminable drugs in biological fluids. In particular, drugs with very poor ultraviolet (UV) molar absorptivities, as well as drugs which by virtue of their specific physicochemical properties result in extremely low recovery values when extracted from biological fluids, have been successfully determined by GC using capillary columns.

The literature is full of such examples and continues to expand at an ever-increasing rate. In addition to the several texts that contain examples of such determinations (3, 81, 82), the reader is referred to several periodicals in which accounts and details of GC assays for drugs (and/or metabolites) in biological fluids are regularly published. These include: *Chromatographia*, *International Journal of Pharmaceutics*, *Journal of Chromatographic Sciences*, *Journal of Chromatography—Biomedical Applications*, *Journal of Pharmaceutical and Biomedical Analysis*, *Journal of Pharmaceutical Sciences*, *Pharmaceutical Research*, *Therapeutic Drug Monitoring*, and LC–GC

FUTURE TRENDS

Although the introduction of HPLC has often been perceived as ultimately replacing GC for use in pharmaceutical analysis, perusal of the current literature and new official compendia clearly indicate that GC is “here to stay.” The notion of an imminent demise of GC appears unrealistic in the light of innovations and applications that continue to expand. Other innovative quantitative techniques with potential for use in pharmaceutical analysis are certainly looming on the horizon. In particular is the technique of high voltage capillary zone electrophoresis. These newer methods, coupled with the now well-established TLC and HPLC methods, will undoubtedly gain more importance and widespread use in the future. However, all these techniques are unlikely to oust GC, since each have their strengths and weaknesses and together compliment the array of techniques and methods for use in pharmaceutical analysis.

Advances in the manufacture of flexible fused silica WCOT columns will almost certainly extend the applications of GC by virtue of their high-resolution capability, while the advent of sophisticated, computerized detectors forecast the improvement in sensitivity and specificity. The use of chiral stationary phases for the resolution of enantiomers is becoming an increasingly

important topic in pharmaceutical analyses. The range and availability of various liquid phases for chiral analysis by GC is bound to make this technique extremely valuable for the assay of pharmaceutical raw materials as well as for use in biological fluids.

Multidimensional and multihyphenated techniques may become increasingly useful, particularly for the analysis of drugs in biological fluids where LC–GC interfacing has a great deal of promise with respect to sample cleanup and preparation time (84,85). GC–MS applications continue to grow in number from the qualitative structural identification point of view, for quantitative analysis that uses SIM (86), and for other quantitative applications of GC (in particular, the increasing use of triple-quad MS/MS spectrometers).

Thus, it is apparent that GC has firmly established itself as a valuable technique for the qualitative and in particular, quantitative determination of drugs. Its application in monitoring impurities, volatile matter, intermediates, and related substances in pharmaceutical raw materials and dosage forms makes it currently the method of choice in this respect. Meanwhile, its increasing use for the quantitative determination of some “hard-to-measure” drugs and metabolites in biological fluids suggest that it is likely to remain an important tool in this arena in the future.

APPENDIX

British Pharmacopoeia (BP) and European Pharmacopoeia (EP) Applications of GC for the Assay; Chromatographic Purity; Identification; Presence of Volatile Matter, Intermediates and Related Substances; Organic Volatile Impurities; Determination of Water; Presence of Isomers and Racemate Ratios; Determination of Alcohol and Miscellaneous Uses of GC in Pharmaceutical Raw Materials and Dosage Forms.

CHIROPTICAL ANALYTICAL METHODS

Neil Purdie

Oklahoma State University, Stillwater, Oklahoma, U.S.A.

INTRODUCTION

The word chiroptical is descriptive of the techniques that use optical detection devices that are selective toward optically active (chiral) materials and/or molecules. They are used for structural investigation and analytical determination. There are three chiroptical techniques:

1. Polarimetry, which deals with the angular rotation of plane polarized light, usually at a single wavelength.
2. Optical rotatory dispersion (ORD), in which the angular rotation of the plane polarized light is measured as a function of the wavelength.
3. Circular dichroism (CD), in which the angular rotation is measured as a function of wavelength, but the light is circularly polarized.

Absorption of light energy is not essential to either polarimetry or ORD. It is, however, an integral part of the CD phenomenon making this method the most selective detector for chiral substrates.

THEORY

Theories of optical activity are described in detail in a number of studies (1–6). The physical phenomenon was first observed during experimental investigations of the transmission of solar radiation through Iceland spar, a natural form of CaCO_3 , by the French astronomer Arago. One year later, Biot (1812) was the first to demonstrate that solutions of certain organic compounds also rotate a beam of incident polarized light. Biot and Fresnel, working independently (1817), reported that the rotatory power of a substance increases as the wavelength is decreased, the phenomenon now called ORD. By 1846, Haidinger had reported differences in the measured absorptions of left and right circularly polarized light, which is the origin of CD.

The first experimental interpretation of the physical basis for optical activity was provided by Pasteur, who observed the hemihedrism of tartrate crystals, which was visually manifest by tetrahedral facets oriented either right

or left with respect to the main crystal surfaces for two crystalline forms. His observation that a linearly polarized beam of light was rotated in opposite angular directions by aqueous solutions prepared from the separated crystal forms demonstrated the first direct connection between macroscopic and microscopic, or molecular, asymmetry.

The first theoretical model of optical activity was proposed by Drude in 1896. It postulates that charged particles (i.e., electrons), if present in a dissymmetric environment, are constrained to move in a helical path. Optical activity was a physical consequence of the interaction between electromagnetic radiation and the helical electronic field. Early theoretical attempts to combine molecular geometric models, such as the tetrahedral carbon atom, with the physical model of Drude were based on the use of coupled oscillators and molecular polarizabilities to explain optical activity. All subsequent quantum mechanical approaches were, and still are, based on perturbation theory. Most theoretical treatments are really semiclassical because quantum theories require so many simplifications and assumptions that their practical applications are limited to the point that there is still no comprehensive theory that allows for the predetermination of the sign and magnitude of molecular optical activity.

A chiral substance is defined by the International Union of Pure and Applied Chemistry (IUPAC) as one that interacts differently with left and right circularly polarized light. Two types of molecular optical activity are recognized: inherent dissymmetry characterized by large rotational strengths and inherently symmetrical, but asymmetrically perturbed, molecules for which rotational strengths are less by a factor of a thousand or so.

The first group is characterized by the absence of a plane of symmetry in the molecule, e.g., hexahelicene. The latter type requires the existence of a chromophore in close proximity to an asymmetric center, such as a carbonyl group adjacent to an asymmetric carbon atom.

Polarimetry

Unpolarized light is thought to consist of an infinite number of time-dependent electric and magnetic fields that vibrate in

phase and at right angles to each other in planes that are orthogonal to the axis of propagation. Only the electric vector is considered in theoretical discussions of optical activity. Linearly polarized light is represented by only one of these planes and is given by the vector sum of two in-phase components of equal intensity that are circularly polarized in opposite directional senses (Fig. 1). The components actually propagate in a helical manner with time; however, the polarization projection on the plane, which is orthogonal to the axis of propagation, is circular, thus, the acquired description of light as circularly polarized.

As linearly polarized light is transmitted through an achiral medium, a single refractive index η is seen by both circularly polarized components, and their rates of propagation are equal. The result is that the vector sum is always a linearly polarized beam oriented along the direction of the incident beam, OO' in Fig. 1a. In contrast, because of the distinctly different interactions that occur between the two helical electromagnetic fields and the helical electronic motion in a chiral medium, two different refractive indices, η_L and η_R , are presented to the coherent beam (birefringence). There being two refractive indices, the left and right components propagate out of phase. On summing the vectors for the transmitted beam, represented for instance by the diagonal of a parallelogram for which OL and OR are adjacent sites, the polarization is still linear; however, a net rotation from the incident direction by an angle equal to α will have occurred (Fig. 1b). Rotational strengths are equal

and opposite for optically active molecular or mirror-image pairs (enantiomers) of equal purity.

The magnitude of the optical rotation α (in degrees) is directly proportional to the refractive index difference and to the sample pathlength d , indicative of the fact that rotation is an extensive property, as shown in Eq. 1:

$$\begin{aligned}\alpha &= (\pi d/\lambda)(\eta_L - \eta_R)(1800/\pi) \\ &= (1800d/\lambda)(\eta_L - \eta_R)\end{aligned}\quad (1)$$

and inversely proportional to the wavelength, in keeping with the observed increase in rotatory power with decreasing wavelength. The quantity $(1800/\pi)$ is included to convert radians to degrees. The magnitude of the birefringence $(\eta_L - \eta_R)$ that produces an angle of rotation equal to 1.0° at the Na-D line (590 nm), for a sample with a 10-cm pathlength, is only 3.2×10^{-8} . Because refractive indices are typically approximately 1.0, it is obvious that the absolute size of the birefringence effect is extremely small.

To normalize rotational values when comparing solutions of different concentrations, the specific rotation $[\alpha] = \alpha/c'd$ was defined, where c' was expressed in g/cm^3 . This unit is an improper choice for making comparisons among substances with different molar masses M , and therefore $[\alpha]$ was replaced by the molecular rotation term $[\Phi] = [\alpha], M/100$. In the older literature $[\Phi]$ was expressed in degrees $\times \text{cm}^2/\text{decimole}$. Division by 100 had no physical meaning whatsoever and was introduced only to keep numbers small. IUPAC has determined that the term molecular rotation is improper and recommended that it be replaced with the more accurately descriptive molar rotation.

OPTICAL ROTATORY DISPERSION

Two types of ORD were first described in 1852 by Biot. In his earliest quantitative experiments on quartz, he demonstrated that the optical rotatory power α varies inversely with the square of the wavelength: $\alpha = \kappa/\lambda^2$. Measurements on a large number of chiral organic compounds, dissolved in solvents both chemically and optically inactive, showed that most of these appeared to obey this law. Originally referred to as the "orthodox" class, these compounds are now thought to produce a plain or normal ORD curve. The distinctive property of the plain curve is that it is always concave to the $\alpha = 0$ -axis, regardless of whether the dispersion is positive (Fig. 2a) or negative. A substantial number of organic molecules, however, were found that did not appear to obey this law but had enormously large rotational powers compared with plain curves, which were limited to relatively narrow ranges

Fig. 1 The incident linearly polarized light OO' is composed of left and right linearly polarized rotating components OL and OR of equal length. In a chiral medium (a), the rotations are in phase, and the result of the two components is always in the same plane as the incident light. In a chiral medium (b), the components rotate out of phase. The resultant, represented by the diagonal of the parallelogram $OLO'R$, is rotated through the angle $+\alpha$ from the incident plane.

Fig. 2 Composite diagram of the three chiroptical dispersion spectra: (a) A positive plain ORD curve; (b) a positive anomalous ORD curve (Cotton effect); (c) a positive CD curve for a single Cotton effect.

in the spectra. Biot referred to this smaller group as the “heretical” class because of their anomalous behavior (Fig. 2b). Tartaric acid was the seminal example. In an effort to more accurately distinguish between the two types, Lowry specified that for normal ORD behavior, the specific rotation α and its first and second derivatives with respect to wavelength must all maintain the same sign throughout the wavelength range over which the medium is transparent. In other words, it is a mathematical statement to the effect that there should be no zero, no maximum, and no reversal of sign for α as the spectrum is scanned, that is, the curve is always concave to the axis (Fig. 2a).

Among the first experimental discoveries regarding the origins of anomalous dispersion was the observation that the effect could be created by mixing pairs of natural products that generate plain ORD curves, provided they were of opposite signs and unequal rotatory strengths, for example, (l)-turpentine and (d)-camphor. This observation was to be of fundamental importance in the subsequent development of theories for anomalous dispersions. For solutions of tartaric acid, a single pure substance, the existence of an anomalous dispersion was more difficult to explain. It was first assumed that an equilibrium mixture of two molecular forms that generate plain curves of opposite signs must exist in solution. Eventually, however, the effect was correctly interpreted as being a consequence of the molecule having two asymmetric centers that give rise to the “required” unequal and opposite rotations.

The development of several mathematical models and interpretations followed, with the best interpretation being proposed by Drude in Eq. 2, where $i = 1, 2, 3 \dots m$:

$$\alpha = \sum_i \left\{ k_i / \lambda^2 - \lambda_i^2 \right\} \quad (2)$$

In modern terms, this is rewritten using molar rotational values by replacing α with $[\Phi]$ and k_i with A_i . Drude originally referred to λ_i as the “characteristic vibrational” wavelength, meaning that there were periods of vibration of the charged particles that, when close to the vibrational period of the incident light, would produce the anomalous effect. Again, in modern terms, these are identified with wavelengths of maximum absorbance in the electronic absorption spectra. Whenever $\lambda > \lambda_i$, that is, the wavelength of observation is outside the range of an absorption band, the Drude equation is reduced to the one-term Biot expression for a plain curve. As the value of λ approaches λ_i , α increases asymptotically, reaching infinity at $\lambda = \lambda_i$. Immediately past the maximum wavelength, α is numerically close to minus infinity, and as λ continues to decrease, the curve follows along an inverse asymptotic path towards zero (Fig. 2b).

The anomalous positive ORD curve in Fig. 2b is rounded at finite values for the maximum (peak) and minimum (trough) extremities. The crossover wavelength, where $\alpha = 0$, generally coincides with the wavelength of the maximum absorbance. An anomalous curve is always superimposed on a fundamental plain curve that is alluded to as the background rotation. Media confirmed to have just a single anomalous dispersion can be solved for λ_i . Historically, this procedure was used to predict the wavelength maximum for an incomplete absorbance band that could not be observed in its entirety because of instrumental limitations. This particular application of ORD is now obsolete.

An anomalous curve is referred to as a Cotton effect in honor of the French physicist Aime Cotton (7) who, in 1892, was the first to point out that the absorption of light energy was the other physical property behind anomalous ORD and CD. Positive and negative anomalous dispersions are equally evident in practice. In ORD, the sign of a Cotton effect, by convention, is defined to be positive when the peak precedes the trough as the wavelength decreases and vice versa. A simple structural way of looking at the origins of ORD in a single molecule is to imagine that the fixed asymmetry of a saturated chiral group induces a degree of dissymmetry into an unsaturated and therefore symmetrical functional group or chromophore. In theory $\sigma \rightarrow \sigma^*$ electronic excitations are possible for saturated molecules for which the theoretical limit of λ_i was determined to be ≈ 150 nm. Chromophores, on the other hand, absorb at much longer wavelengths in the easily accessible range of modern instrumentation. The closer 150 nm is approached, the harder it is to measure a spectrum. Whenever the induced dissymmetry is opposite in sign to the fixed asymmetry, anomalous dispersion is produced. The mutual proximity of the asymmetric center

Fig. 3 The anomalous ORD spectrum consisting of several overlapping Cotton bands of the unsaturated rigid ketone, bicyclo(2,2,1)hept-5-enone, which shows how complex the spectrum can be, even for a single molecule.

and the chromophore is a necessary prerequisite to CD induction. Dissymmetry is the preferred description for the induced chirality because the chromophore might well have a high degree of axial symmetry. How this perturbation might occur has never been satisfactorily explained.

Fig. 2b is an idealized illustration of a single, uncomplicated Cotton effect. In reality, the occurrence of a complete curve in the electronic spectrum is rare. Complete dispersions are more likely to be observed in the vibrational spectral range because of the increased spectral resolution. However, even there, dispersions are too often complicated by extensive band overlap. The same is true for electronic spectra where hidden absorption bands coupled vibronic excitations and interferences from bands associated with other chiral chromophores contribute to producing anomalous ORD curves that are so complex they have little utility in quantitative analytical applications (Fig. 3).

CIRCULAR DICHROISM

Because absorption is a prerequisite to CD activity, the phenomenon is limited to only those wavelength ranges that encompass an absorption band in any part of the

electromagnetic spectrum. Outside the range of absorption, the CD signal is zero, which is the first important advantage CD has over ORD as an analytical detector. It should be emphasized, however, that the absence of a band is not evidence of the lack of chirality in the substrate.

At the time that Cotton was correctly interpreting the physical origins of anomalous ORD behavior, he proposed that there is also a difference between the absolute absorbances of the two circular polarized beams by a chiral medium (dichroism) and that the magnitude of the dichroism is proportional to the absorbance difference. Convention has dictated that the difference is always written as the absorbance of the left rotating beam minus the absorbance of the right, $\Delta A = A_L - A_R \neq 0$. Using the Beer–Lambert law to convert A to molar units, the dichroism expression can be rewritten as $\Delta \epsilon = \epsilon_L - \epsilon_R$, where ϵ has the units of L/mol cm.

A single positive CD band is shown superimposed on the anomalous ORD spectrum in Fig. 2c. The wavelength of the maximum CD coincides with the crossover wavelength of the ORD dispersion. Shorter lengths for the vectors OL and OR compared with the incident vector in Fig. 1 are used to convey the fact that absorption has occurred. The absorbance difference at a given wavelength is then represented by unequal vector lengths $OL \neq OR$. The resultant of OL and OR, given by the instantaneous diagonal vector OO' of the parallelogram OLO'R, no longer oscillates in a single plane, but traces out the perimeter of an ellipse as OL and OR rotate around an angle 2π . The transmitted beam is rotated by the angle α from the original plane of polarization (owing to birefringence) and is elliptically polarized owing to dichroism (Fig. 4).

The eccentricity of the elliptically polarized light is characterized by the term ellipticity Ψ equal to the arctangent of the ratio of the minor to the major axis of the ellipse and given by OA/OB in Fig. 4. Because the ratio $(\Delta \epsilon / \epsilon)$ necessary to produce an observable CD signal is as small as 1 part in 10^7 , the ellipticity is approximated almost exactly by the expression $\Psi = \pi(\epsilon_L - \epsilon_R) / \lambda$, which is entirely analogous to Fresnel's equation that relates birefringence to α and points up the common origins of anomalous ORD and CD.

In keeping with the older definitions of terms that are part of polarimetry, there are definitions for specific ellipticity $[\Psi] = \Psi \cdot c \cdot d$, and molecular ellipticity $[\Theta] = [\Psi] M / 100$, where M is the molar mass. With appropriate substitutions, the molecular ellipticity can be expressed in terms of ϵ , namely $[\Theta] = 3300(\epsilon_L - \epsilon_R) = 3300\Delta \epsilon$. The numerical constant is the result of all the physical conversion factors. The survival of these arcane units is a

Fig. 4 Production of elliptically polarized light in CD. The direction of polarization of the incident beam is OO' . The unequal vectors OL and OR represent the difference in absorbances of the left and right rotating component beams. The angular rotation is $+\alpha$, and the ellipticity is the arctan (OA/OB) .

consequence of the wealth of informational data already in the literature. The disclosure that CD is no more than a modified absorbance technique should ultimately motivate investigators to adopt the term molar ellipticity, Θ_M , in the CD analog of the Beer–Lambert law, that is, $y = \Psi = \Theta M c d$.

Anomalous ORD and CD both originate from light absorption by a chiral species and as such contain the same information. A mathematical equation, the Kronig–Kramers transform, relates one to the other over the wavelength range of the absorption, namely, $[\Theta(\lambda)] = -2/\pi [\Theta(\lambda')](\lambda'^2/\lambda^2 - \lambda'^2)d\lambda'$. When the appropriate substitutions are made, the equation relating ORD to CD reduces to $\Theta = 40.28\Delta\epsilon$.

Because all the rules that apply to absorbance detection apply equally well to CD, it is convenient to think of CD as a modified form of absorption spectrophotometry. Spectra are temperature- and pH-dependent; nonlinear correlations of signal versus concentration are commonplace and are produced for the same reasons, such as chemical equilibria, polychromatic radiation, stray light, etc. Fluorescence emission CD (FDCD) spectroscopy is observed whenever an

analyte meets all three of the structural prerequisites simultaneously, either intrinsically or extrinsically. Therefore, anyone with experience in absorption and emission spectrophotometries can easily become acquainted with the experimental capabilities of CD. Similarities end there, however, and the differences are what make CD detection unique, especially the enhanced selectivity that arises from the fact that CD bands can be positive or negative in sign. Electronic absorption bands are generally broad and lack the kind of resolution associated with the infrared range. In contrast to visible-UV absorptions, however, exciton coupling can divide CD bands into two sub-bands of opposite sign and unequal intensity separated by a characteristic crossover wavelength where the signal is zero (6), resulting in narrower bands than those given by absorption. Circular dichroism is used most often for the analysis of bulk samples and has seen limited use in liquid chromatography and capillary electrophoresis.

CD activity can be induced into molecules that are either chiral or achiral and is generally referred to as extrinsic CD. For chiral species, intrinsic and extrinsic CD effects are additive. Compared with intrinsic CD, the extent of extrinsic or induced chiroptical effects is small. One way to induce activity is to apply a static magnetic field whose strength is on the order of 10–20 kGauss. Magnetically induced CD (MCD) was originally described by Verdet and correctly interpreted by Faraday in what has become known as the Faraday effect. A magnetic field of sufficient strength splits the degeneracy of the electronic ground and/or excited states (the Zeeman effect), resulting in absorbance differences between the two circularly polarized beams. The effect is entirely general and can be observed in every dielectric substance that transmits light. The magnitude of the effect depends on the relative orientations of the light path and the magnetic field strength and is at maximum when the fields are parallel. For a fixed geometry, the maximum signal is proportional to the sample pathlength and the analyte concentration. Poor sensitivities and even poorer selectivities associated with MORD and MCD make them unacceptable as analytical detectors.

A second way to induce chiroptical behavior is to associate a chiral center on one molecule with a chromophore on another by some aggregation or complexation reaction. If the chiral moiety is CD-inactive, only the resultant complex exhibits CD activity. The intensity of the induced CD signal is determined by two factors: the concentration of the complex that is formed and the magnitude of the induced $\Delta\epsilon$ term. Magnitudes and selectivities of chemically induced CD are much greater than those of MCD and have correspondingly

higher potential for analytical applications. Typically, the correlations of signal amplitudes with analyte concentrations are nonlinear.

INSTRUMENTATION

The basic instrumental needs for chiroptical methods are virtually the same as for other spectroscopic methods, namely, a stable unpolarized illuminating source of sufficient intensity, a wavelength-selection device, sample holder, and detector; polarizing elements are essential. Because the only parameter measured in polarimetry and ORD is rotation, the polarizing elements are common to both. A monochromatic source, such as an Na or Hg lamp, is all that is required for polarimetry. Deuterium or halogen lamps are of sufficient intensity for ORD, but highly intense (150–450 W) Xe arc lamps are needed for CD.

Polarizing elements are transparent rhombs constructed by joining together two triangular prisms cut from a single crystal of calcite or quartz. The junction between the two parts may be just air or a light-weight balsam cement. The purpose of the junction is to physically separate the ordinary and extraordinary rays of the linearly polarized light beam, allowing only one ray to pass while the other is selectively reflected in a direction at a right angle to the first. Often, the reflected ray is fully absorbed to eliminate any interference with the transmitted ray. An excellent historic account of the assembly of the parts into working polarimeters is given by Lowry (1).

In polarimetry and ORD, the sample is placed between the first polarizing element (the polarizer), which remains fixed, and the second element (the analyzer), which can be rotated about the axis of propagation. Maximum intensity of the transmitted light is observed when the principal axis of the polarizer and analyzer are colinear and exactly parallel. The intensity is zero when they are crossed; that is, when the principal axes are orthogonal to each other. The most accurate way to determine the rotation angle α is to set the polarizer and analyzer in the crossed position using an achiral substrate and to measure the extent to which the analyzer has to be turned to restore the optical null position when the achiral sample is replaced by a chiral substrate.

Optical rotations are temperature-dependent. For the most accurate work, sample cells must be thermostatted. Solution concentrations are typically above 0.2 M for polarimetric detection, and pathlengths range from 1.0 to 100 mm; volumes vary from 0.1 to 50 ml. Because rotations increase in magnitude with decreasing wavelength, the best sensitivities using conventional light

sources are achieved in the UV. Accuracies are reported to be on the order of $\pm 0.2\%$ for rotations $> 1.0^\circ$. Only the most sophisticated high-sensitivity polarimeters meet the requirements for chromatographic detection. With a stable laser system as the illuminating source, rotations as small as 10^{-10} to 10^{-11} radians can be measured fairly accurately. High sensitivities are critically important in chromatography because concentrations of eluted components are very low, being limited by the retention capacity of the column materials, and because pathlengths, viewed across the eluant exit tubes, are very short (8).

The first commercial ORD spectropolarimeters appeared in the 1950s but are no longer available. The ORD capability is typically offered as an add-on to a CD spectropolarimeter.

At present, technical difficulties associated with scanning chiroptical methods prevent the use of diode-array detection, and therefore wavelength is selected in CD with a scanning double monochromator set-up (Fig. 5). The block diagram for CD differs from ORD instrumentation by the addition of an electro-optic modulator, placed immediately after the linear polarizer, to generate the phase-separated left and right circularly polarized component beams that are the origins of the elliptically polarized light beam. The physical parameter that was measured in the first CD instruments was the ellipticity of the transmitted beam (Fig. 4). Greater accuracy and greatly improved sensitivities are achieved if the absorbance difference is measured, which is the procedure preferred by every contemporary CD instrument manufacturer.

Because of significant losses of radiant power on polarization and transmission through the double monochromator system needed to keep stray light to an absolute minimum, the light sources for CD detection must be intense. As a consequence, instrument compartments are purged with nitrogen to remove ozone that might be produced by the high-intensity radiation of oxygen. The detector is a photomultiplier tube. Wavelength ranges on commercial instruments extend from 180 to 850 nm. Instruments for the vibrational spectroscopy range are still only custom built. The ellipticity, or $\Delta\epsilon$, scale should be calibrated daily against selected standards. Scale calibration is wavelength-dependent, and whenever the range of study is very broad, the use of more than one standard is recommended. Those most commonly used are androsterone, pantoylactone, (+)-camphor-10-sulfonic acid, and ammonium camphor-10-sulfonate for the near-UV, and alkaline nickel(II) tartrate in the visible.

With absorbance differences on the order of only 1 part in 10^7 for CD activity, the ratio of transmitted intensities for the left and right circularly polarized beams (I_L/I_R)

Fig. 5 Block diagram for a commercial double-monochromator CD spectropolarimeter. M = various mirrors; S = slits; P = polarizing elements; LS = light source; SC = sample; PMT = photomultiplier tube; L and F = lens and filter, respectively; EOM = electro-optic modulator.

is essentially one because the errors in $\Delta\epsilon$ would be very large if I_L and I_R are measured directly.

$$\Delta\epsilon = (\epsilon_L - \epsilon_R) = [(1/c \cdot d) \log(I_L/I_R)] \quad (3)$$

The problem is overcome instrumentally by measuring the intensities I_L and I_R separately, at a frequency of 5 kHz. This has the effect of producing an AC voltage proportional to the CD signal, riding on top of a steady-state DC component proportional to the total absorbance at each wavelength. The independence of I_L and I_R from the steady-state DC voltage indicates that the size of a CD signal is not dependent on the absolute magnitude of the absorption, and relatively strong CD signals can be obtained from overall weak absorbers. Although an absorbance difference is measured in CD detection, the total absorbance by the substrate and matrix is still a limiting feature because it can affect the intensities of the transmitted beams to be measured. Excessive amplification of very weak signals increases the noise level and adversely affects the quality of the CD signal.

The principal electronic excitations in the accessible UV range that lead to absorption by organic molecules are

the $\pi - \pi^*$ transitions associated with the aromatic ring and the $n - \pi^*$ transitions of carbonyl functional groups. Excitations associated with $\pi - \pi^*$ transitions have a high probability, and absorbances are highly intense. To preserve the signal quality, solutions must be very dilute and/or pathlengths must be short, which is the second advantage that CD has over polarimetry and ORD. The photomultiplier (PMT) measures the total transmitted intensity and is incapable of discriminating between chiral and achiral species. Besides affecting the signal/noise ratio, excessive absorptions reduce the linear dynamic range of the detector. At the low concentration end, the determining factor is the very small size of the CD signal, and the upper limit is determined by the total absorption. Ranges are often much narrower than they normally are using absorption detection.

Current CD instruments commercially available for analytical applications are limited to the electronic excitation range of the electromagnetic spectrum. The more sophisticated of these have the added capability of pulling an eluate from a chromatographic separation off-line into a microcell attachment where, instead of limiting

detection to just one wavelength, a partial CD spectrum can be measured. Volumes can be as small as 10 nL (8). Instrumentation for the measurement of vibrational CD (VCD) and Raman optical activity (ROA) are still custom-built, although the prospects for their commercial development in the not too distant future are bright. A major disadvantage is, of course, that the emission intensities of tunable IR sources are generally weak.

An intriguing recent development in CD detection is its extension to the wavelength range of soft X-Rays using a synchrotron source (9). Although this might never become a routine analytical method, it has been speculated that from CD measurements made in this range, it will at last be possible to indisputably determine the absolute conformation of a chiral molecule of any size in solution. This would make it superior to NMR detection, which is limited to small molecules and single-crystal X-ray structure analyses, in which, for the want of other methods, structures are usually assumed to be the same in solution.

ANALYTE SELECTION

In deciding whether analytes are CD-active, it is not always a simple matter to inspect a molecular formula and be certain that the chromophore and the chiral center are mutually located in a manner that produces activity. Even if the molecular structure suggests that a chirally perturbed chromophore is present, the substance might only be available as an achiral racemic mixture and therefore is not detected by CD.

Optimum wavelength ranges for CD detection are those where the absorption is minimum and the CD signal maximum. Absorptions for $n - \pi^*$ and $\pi - \pi^*$ transitions are generally weaker at wavelengths longer than 230 nm, where they appear as shoulders on the edges of the intense bands that reach a maximum at shorter wavelengths. Frequently, CD bands in the range of 230–340 nm are intense enough to allow quantitative analysis, e.g., for testosterone and dihydrotestosterone (Fig. 6).

Electronic excitation energies are shifted to longer wavelengths as the extent of molecular conjugation increases. The molecular symmetry that accompanies the structural planarity created by conjugation might reduce the number of potential achiral centers and the chances of observing intrinsic CD activity, for example, in organic dye molecules. Strong absorptions by dyes, however, are exploited by associating them with a chiral molecule to induce an extrinsic CD activity in the longer wavelength range, where passive absorption by the matrix is less of an interference. Other absorbers of this capability are colored

Fig. 6 Demonstration of the strong similarity between the absorbance spectra for (a) dihydrotestosterone and (b) testosterone in methylene chloride in contrast to their CD spectra (c) and (d), respectively.

chiral metal complexes that have the special advantage that their absorbances are generally of much lower intensity than those of organic dyes.

Similarities between CD and absorbance methods are also found between CD and fluorescence and CD and circularly polarized luminescence (CPL). Three prerequisites are needed to produce FDCD and CPL activities (8). Intense emission signals normally associated with fluorescence are attractive because limits of detection are lowered considerably. FDCD finds more uses as a chromatographic detection device. A CD signal is usually induced by some kind of molecular complexation reaction. Association can be with a simple molecule or with an aggregate of molecules, such as chiral micelles, which are known to be fluorescence enhancers. In cases of color induction combined with fluorescence induction, FDCD can lead to even higher levels of selectivity among analytes that have been derivatized by the same color reagent.

Selectivity enhancement is a result of a number of circumstances. For example, not all of the sub-bands in the absorption or fluorescence spectrum of the derivative are necessarily CD-active; because only the chromophore next to the chiral center must fluoresce for CD activity, all other fluorescence that centers on the analyte, or in the matrix, will not interfere with the FDCD signal, and if a chiral center is lost in the derivatization process, that molecule will be removed from the list of interferences.

CHIROPTICAL DETECTION IN CHROMATOGRAPHY

Only polarimetry and CD find practical use as chromatographic detectors (8). Important parameters to consider in modifying chiroptical detectors for use in chromatography are the very small sample volumes involved, which today can be handled with relative ease, and the very short time intervals that separate consecutive peaks, which has not been, and probably never will be, totally resolved. Peak overlap remains a significant problem. In molar terms, limits of detection are not particularly impressive, for example, micromolar levels, but in volumes as little as 1.0 μl , the limits of detection are actually at the nano- to picomole level and sometimes lower (10–14). Engineering priorities are to develop the technology to focus the beam on such small targets while maintaining the high level of radiance needed for chiroptic detection. CW lasers are an obvious place to start, but source noise and instability are problems to contend with (14). By exploiting the added radiance of pulsed lasers, limits of detection can be stretched to even lower levels. Laser sources, however, are limited in the number of their output wavelengths. Dye lasers offer the best, albeit still very narrow, ranges (approximately 60 nm). Current CD instruments, in which the source is laser illumination, really do operate at just a single wavelength, depriving the detector of its ability to identify an analyte.

Options for multichannel LC–CD detection do exist (14–16). Stopped-flow accessories for commercial instruments are available that allow part of an eluted fraction to be taken off-line into a microcell placed in the regular sample compartment where data are measured in the normal way. The method still requires rapid scanning capabilities. Repeated injections and multiple scans can be averaged to improve the quality of the signal. A major deterrent to the progress in the early development of HPLC–CD detection was the lack of a dedicated instrument at a reasonable cost, the only option being a fully equipped CD instrument.

In 1998, Jasco International Co. introduced the first dedicated commercial polarimetric detector, the OR-990, and the first dedicated CD cum absorbance detector, the CD-1595, for HPLC. The CD detector operates in the 220–420 nm range, with a 20 nm bandwidth. The illuminating source is a 150 W Hg–Xe lamp. Injections are typically in the microgram range. Minimum detectable amounts are on the 0.1-ng scale. The sensitivity of the CD detector is typically 200 times higher than that of the OR-990 detector but of a factor of four lower than the absorbance detector of the CD-1595. The latter is the

limiting factor in the combination of CD with absorbance detection when applied to enantiomeric purity measurements. This last assay has taken on considerable new meaning with the obsessive focus on measuring the enantiomeric purities of chiral drugs in the biotechnology and pharmaceutical industries.

Eventually these devices may turn out to be the starting point for the development of CD diode-array detectors. Adjusting the scanning speed for on-line, wide-spectrum CD measurements is a formidable problem. A major reason for the problem is the incongruity between the time it takes to accumulate CD data, even for just one spectral “pass” using the very best currently available diode array technology, and the typical dispersion time between chromatographic peaks. The situation may very well change as faster electronic detection devices become available.

If all the components of a sample loaded on an HPLC column are baseline-separated, any conventional detector will work, unless the object of the separation is to determine or confirm the stereochemical conformation of an enantiomer. In achiral systems, (solvent and/or stationary phase) enantiomers have identical retention times and are not separable. The problem has a solution if two detectors are used in series, e.g., CD and absorbance (17–19). Because the enantiomers elute together, the absorbance detector measures the sum of their concentrations, and the CD detector measures the difference ΔA . Solving the simultaneous equations gives the concentrations for both enantiomers.

Historically, the experimental limitations of this procedure give totally meaningless results when enantiomeric ratios are greater than 95:5, or within 5% of being racemic (20). Concepts that have evolved as potential solutions to these experimental limitations making them capable of improving on the accuracies of enantiomeric purity determinations are the *g*-factor and principal component analysis (PCA) treatments of eluted band intensities as a function of time (21, 22). These are especially useful in cases in which bands are asymmetrical (22), which is frequent. The *g*-factor is defined as the ratio of the CD intensity to the absorbance intensity $\Delta A/A$. One attribute of this factor is that for an enantiomerically pure material, the *g*-ratio does not change with concentration. Should a change in the *g*-factor occur during the elution of a band, it is clear evidence for an enantiomeric impurity. Ideal traces documenting the total resolution of bands for two pure enantiomers in a racemic mixture would consist of two horizontal lines with constant *g*-values of equal and opposite signs. Over the time interval between the elutions, the traces are separated by signals that are excessively noisy. This occurs because calculated

g-factors in the ranges in which no CD-active species is being eluted correspond to zero divided by zero. With PCA, the number of components that are coeluted can be derived by reduction of a matrix of signal intensities versus concentrations versus time data for a series of solutions with prepared compositions (21).

Ostensibly, the better alternative is to separate the enantiomers on a chiral HPLC system, typically done by reacting both enantiomers of a racemic mixture with a third chiral species. The chiral derivatizing agent is an integral part of either the mobile phase or the stationary phase (19). The products are two diastereoisomer derivatives with different retention times. The same principle was used in classic experiments in which, for example, (–)brucine was added to separate enantiomers by fractional crystallization. It is still the only viable option to discriminate among enantiomeric forms by NMR. The numerous problems associated with chiral chromatographic methods are familiar (20, 21):

- The number of chiral derivatizing agents that are 100% enantiomerically pure is extremely small.
- Differences in retention times are very small if the material has several chiral centers.
- In practice, chiral solvents can be used as mobile phases only once.
- Even if derivatization is accomplished, baseline separation is not guaranteed.
- Racemization of the analyte may occur on the column during elution.

The protocol for separating a partial racemic mixture calls for the chromatographic conditions to be modified in such a way that the minor component elutes first (23) and is not lost in the trailing edge of the band for the major component. Errors encountered in the determination of enantiomeric excesses when they are in the range of 98–100%, or close to unique protocol is required for every chiral analyte assayed by chiral-HPLC, requiring considerable development time and constant review of the procedure.

DIRECT CHIROPTICAL DETECTION

In this context, direct means separation of the substrate, except solvent extraction, is not a part of the analytical work up (24–26). Only CD has the necessary selectivity to function as a direct detector. Chiral molecules that do not absorb (e.g., most simple sugars) do not interfere. Achiral molecules that absorb interfere to the extent that their absorption lowers the signal/noise ratio and the limits of

detection. Naturally occurring pigments and coloring agents added to pharmaceuticals are among the worst interferences.

Overlapping bands from multiple CD-active analytes are also a concern, although there is less of a tendency for this to happen with CD compared with absorption because bands are generally narrower and often have opposite signs. Curve-fitting algorithms might be used to resolve overlapping bands, but these kinds of solutions often lead to ambiguous results. More and more attention will be given to pattern-recognition strategies that involve data analyses that use chemometric methods such as principal component analyses and artificial neural networking (27).

Molar ellipticities in the preferred wavelength range of 230 to 340-nm for underivatized analyses typically differ by only a factor of two or three. By comparison, linear dynamic ranges are much greater than this, and the limiting property in discriminating among CD signals is the analyte concentration rather than the rotational strength of the chiral chromophore. Limits of direct CD measurements made on bulk samples using direct transmission detection are similar to those for absorbance, approximately 100 nM for a 1.0-cm pathlength.

REFERENCE CD SPECTRA

There are no comprehensive data files for CD spectra for standard reference materials (SRM) that compare with the exhaustive libraries which have been compiled for absorbance data in the electronic and vibrational spectroscopy ranges. Analysts are required to create their own CD spectral files using SRM prepared by the usual purveyors of fine chemicals. A significant problem with an SRM is that although it might meet the industry specifications for chemical purity, its enantiomeric purity is open to question. The few cases in which absolute enantiomeric purity might be assured involve natural products whose syntheses are under total enzymatic control. To prove 100% enantiomeric purity is beyond current capabilities (20). The problem is compounded even more with the risk that the material might racemize after its extraction from its natural environment. Therefore, it is not possible to assume absolute enantiomeric purity with firm conviction.

The superficial observation that CD spectra for enantiomers are exact mirror images of each other is only true if the two SRM used to calibrate the CD have equivalent enantiomeric purities. And even if the spectra are exact images, the evidence is not irrefutable proof that both SRM are 100% enantiomerically pure.

Added complications arise when an analyte molecule has two asymmetric centers for which there are a total of four optical isomers (R,R; R,S; S,R; and S,S). Together they constitute two pairs of diastereoisomers for which there are two pairs of "equivalent" CD spectra. It is conceivable then that the wrong analyte could be identified and assayed. The practical solution of these disconcerting uncertainties is to run regular checks on the reproducibility of the spectrum for a chemically pure SRM that has been "defined" to be enantiomerically pure. This is done by adding spectral data for every new issue of an SRM, supplied from different product lots by different manufacturers, to an ever-increasing data pool and periodically updating the statistically averaged spectrum as the reference spectrum. The inability to get standards of absolute enantiomeric purities takes on an even greater practical significance when attempts are made to assay enantiomeric excesses or enantiomeric purities in mixtures of isomers that may have been produced synthetically.

APPLICATIONS

The ubiquity of the aromatic ring and carbonyl chromophores in the molecular structure of natural products means that the number of potential analyses is enormously large. Djerrasi (2) pointed out the analytical potential of chiroptical methods as long ago as 1960, but even now, the number of investigations is small, which is explained in part by the enormity of the field of separation sciences. Most analysts would argue that the obsession with separation is because problems with interferences are minimized. On the other hand, for many of these processes, their potential was illustrated using carefully chosen synthetic laboratory mixtures, most of which were so simple they did not even begin to address the complexities that are encountered in the analysis of real samples.

The emphases of this section reflect the author's own special interests in using CD detection to directly determine chiral substrates. The majority of the systems described are drug substances. Direct analytical applications over the last 20 or so years have clearly demonstrated that a priori expectations of serious interference problems are ill-founded. Analytical sensitivities similar to those for absorbance spectrophotometry are readily accessible, and a high degree of analytical selectivity is obtained because of that very same property that makes ORD and CD such useful structural tools, namely, the sensitivity of a chromophore to its chiral

environment (3, 6). Substrates are organized into three groups:

1. Those with chiral chromophores that absorb in the near-UV
2. Those that are either chiral or achiral but do not absorb and are derivatized to absorb in the visible
3. Those that are achiral and absorb and have optical activity induced by interaction with a chiral host.

CHIRAL CHROMOPHORES THAT ABSORB IN THE NEAR-UV

The major analytes in this category are the alicyclic compounds (alkaloids and terpenes); heterocyclic compounds (barbiturates, benzodiazapams, indole alkaloids, quinolines, nucleic acids, and nucleotides); aminoacids and peptides; oligopeptides; and proteins (globular, nucleo-, and lipo-); saccharides and polysaccharides; and condensation products of saccharides with all the other analytes, e.g., glucuronides and glycoproteins (26). Thus far, most analyses have been done on solid and solution forms of the drug substances. A few illustrations are reported in which CD was used in the direct analysis of biological extracts.

Morphine Alkaloids

The first series of compounds assayed directly by CD detection were the morphine alkaloids. They were supported in aqueous solutions (28), in a chiral cholesteric liquid crystal solvent (29), and mixed in pellet form with solid KBr (30). Contrary to expectations, the homogeneous aqueous solution medium gave the best selectivity among 10 related opiates and the most quantitative results. The pH-dependence of phenol substituted analogs, which in some instances caused the sign of the CD signal to invert, enhanced the selectivity. Heroin was assayed both directly and as the morphine hydrolysate (31). Direct multicomponent analyses were made for prepared mixtures of morphine, codeine, thebaine, noscapine, and opium extracts (32).

Aromatic Amines

The strong structural similarities and the proliferation of enantiomeric forms in the phenethylamine and catecholamine series are major reasons for the considerable difficulties encountered in their analyses (20). Absorbance bands in the 250- to 320-nm range are identified with the aromatic ring and are nondiscriminatory.

Chiroptical detection methods have a slight edge over absorbance and a large advantage over electrochemical detection because of the birefringence factor. An ORD detection assay was developed to analyze mixtures of ephedrine and pseudoephedrine (33). An unprecedented advantage was found in the determinations of amphetamine and methamphetamine in cases in which achiral excipients such as lidocaine, procaine, and benzocaine had been added to deliberately confuse the assay by absorbance detection (34). These additives have absorbance spectra and retention times in achiral liquid chromatography that are too similar to the analytes.

Antibiotics

All the tetracyclines have intense visible CD spectra, with some degree of discrimination among them possible (35). The β -lactam antibiotics have very similar near-UV absorbance spectra, making some kind of separation the method of choice for their determination. Discrimination between the penicillin and cephalothin groups by CD detection, however, turned out to be an elementary exercise when mixtures of Pen-V and cephalothin were simultaneously determined with equal imprecisions in prepared laboratory mixtures (36). In contrast, discriminations among individual members of either β -lactam group is a very difficult prospect that will, in all likelihood, require a prior chemical derivatization. An ORD study reported the discrimination between the neomycin B and C aminoglycoside antibiotics. However, the strong similarities between the absorbance and CD spectra for the polymixin and bacitracin antibiotics (30) make their discriminations by direct assay impractical unless there is first a derivatization step.

Alkaloids

Other alkaloids assayed with varying degrees of success include the quinine–quinidine, cinchonine–cinchonidine, digoxin–digitoxin, L-Hyoscyamine–atropine, and pilocarpine–isopilocarpine diastereoisomeric forms. Being diastereoisomers, these have different chromatographic retention times, yet their assays are confused when compositions of the enantiomeric mixtures change. Prepared binary mixtures of the first two pairs of diastereoisomers were easily quantified using direct CD detection (37). Observed signals for the digoxins and pilocarps, on the other hand, are so weak that the best possible analysis was qualitative identification. The CD spectra for the colchicine, strychnine, brucine, and tubocurarine alkaloids, all

potent poisons, have been characterized in strong aqueous acids (38, 39). No reports of their being assayed by chiroptical methods have appeared.

Vitamins

In the area of vitamin analyses, CD spectra have been characterized for the water-soluble vitamins B2 and C. When they occur together, their distinction by direct measurement is an elementary procedure. Both were successfully assayed in the extracts of pharmaceutical preparation, as was B12 (40). Analysis of the fat-soluble D2 and D3 vitamins (ergocalciferol and cholecalciferol) has not been equally successful (38). Vitamin D extracted from natural sources has a single conformational stereochemistry that is one of several isomers produced in synthetic preparations. To certify that the natural form is present in a synthetic product, where it can be accurately assayed in the presence of the other isomers, is a formidable analytical task. Whether direct CD detection can satisfactorily solve it is currently unknown. A prior nonselective derivatization reaction might be required on all isomers. The A and E vitamins are achiral and not subject to chiroptical detection unless first derivatized by reaction with a chiral host.

Steroids

The seminal work on steroid analyses using chiroptical detection was done by Djerrasi by the determination of hecogenin acetate in the presence of tigonenin acetate (2). Every steroid is chiral and therefore amenable to polarimetric detection after chromatographic separation. Chromophores are fairly uncommon, and analysis by ORD or CD is therefore less suitable. The only unsaturation in the cholesterol molecule, for example, is the isolated Δ^5 -double bond, which has an absorbance maximum at 205 nm. Unsaturation coupled with chirality provides some selectivity, as ably demonstrated by the work of Potapov for analogs of progesterone (41). Even simpler than that is the direct discrimination between the ketosteroids testosterone and dihydrotestosterone, which have opposite signs in methylene chloride solution (Fig. 6).

Gergely promoted the development of ORD methods for the Δ^4 -3-Ketosteroids and the 17-Keto- and 17-Ethynyl derivatives (42). The 17-Keto derivative is often present as an impurity in the manufacture of 17-Ethynyl-substituted steroids and is easily quantitated by mathematically fitting the spectrum for the mixture using weighted spectra for the components or by measuring the spectra in two solvents. In the second option, data at two wavelengths are used to

prepare simultaneous equations that are solved for the concentrations of both components. The latter was used to quantitate mixtures of corticosteroids and Δ^4 -3-Ketosteroids (42). For the most accurate results, however, chemometrics methods are recommended with full spectral data.

Carbohydrates

Although included in this subsection, the only carbohydrates that meet the condition of absorbing in the near-UV are the keto-, amido-, and carboxylate-substituted sugars (43). Fully saturated sugars absorb only at wavelengths less than 200 nm and in general have incompletely developed spectra, with many not reaching a maximum signal. In the near-UV, excellent analytical data have been obtained for the in situ determination of D-fructose in honey (44) and of the *N*-Acetyl content of chitosan in crustacean shells (45). Simple sugars commonly exist in the form of equilibrium mixtures of open-chain and cyclic anomers (46), in which equilibrium must be established and the temperature controlled for the most accurate and reproducible measurements. Aldoses are typically determined by high-performance liquid chromatography (HPLC) using absorbance detection at approximately 300 nm. Polarimetry can be, and has been, used whenever information on the enantiomeric forms of the eluants is needed. Kuo and Yeung combined both these detectors for the analysis of several saccharides in laboratory mixtures. An advantage is that the focus is narrowed to cover only chiral absorbers, which simplifies the analytical identification of the eluates. Of the systems in which HPLC with CD detection was used (47), the most common are the simplest ketoses, D-fructose, D-tagatose, D-sorbose, turanose, D-ribose, and vitamin C.

Aminoacids, Peptides, and Proteins

Most of the findings related to CD detection of steroids and carbohydrates apply equally well to these analyses. Without derivatization, only aminoacids with aromatic side-chain substituents are CD-active in the near-UV. Signals are generally weak, and enantiomeric purity measurements using polarimetry detection are not quantitative. Peptides and proteins have stronger rotatory powers with obvious potential for clinical analyses. Nevertheless, the major exploitations of these data are toward elucidating secondary and tertiary structural information in aqueous media (20, 48, 49). With respect to analytical applications, there is a larger role for these macromolecules as auxiliary or host substrates in determining low-molecular-weight

substances that bind to the hosts in stereocontrolled ways, such as warfarin to human serum albumin for which FDCCD is the preferred detector (50).

The ubiquitous involvement of these materials in chirality induction for the purposes of assaying small molecules, determining enantiomeric purities, quality control, and quantitative structure-activity relationships (QSAR) is reviewed later in this article. The detector that is common to all these applications is CD.

Natural Products in Plant Extracts

A special example of the analytical selectivity of CD is its ability to directly assay natural products in plant extracts. Because there are no reference standards for plant materials, an assay is deemed to be successful if the results lie within the expected compositional ranges for that material (51). Analyses are not fully quantitative. Direct assays have been described for tetrahydrocannabinol and cannabidiol in marijuana extracts (52); S-Nicotine in leaf extracts from tobacco and tobacco products (53); Pen-V extracted from a crude fermentation broth (36); vitamin C from a variety of whole fruits, fruit juices, and whole vegetables (40); reserpine alkaloids from *Rauwolfia* (54); pyrethroid insecticides (11); and amaryllidacea alkaloids (17); atropine from *digitalis* (24); and humulone from hops (24). Obviously, the most serious interferences would be from the absorbance by the plant pigments and light-scattering from suspended materials. The CD assays offer the advantage that the pigments are not fully extracted into the selected solvents, leaving the near-UV virtually transparent to absorption.

Exceptions to this last observation are encountered when the colored materials happen to be present in the same phase where, because of their excessive absorbances, the signal-to-noise ratio is decreased. This kind of complication was successfully handled in direct analytical assays devised for lysergic acid diamide (LSD) (55) and phencyclidine (PCP) in illicit drugs spiked with intensely colored dyes (56); for L-Cocaine, morphine, and methadone in the pharmaceutical product commonly referred to as Brompton's cocktails (57); and for D-Pseudoephedrine in children's Sudafed (37).

SUBSTRATES MADE CD-ACTIVE BY COLOR INDUCTION

From what has been learned from the near-UV studies, the selectivity and the sensitivity of CD detection are greatly enhanced if the CD-active absorption bands are shifted

from the wavelength range where the matrix absorbances are highest. With a few exceptions, the range of least interference is the visible. Wavelengths are shifted by using selective color or fluorescence derivatization reactions on chiral analytes as they exist in the matrix.

Color derivatizations can be broadly divided between reversible and irreversible reactions. Reversible reactions typically involve some kind of complex formation equilibrium. The color originates on the host and is imparted to the analyte on the formation of the complex. The combination of chirality and absorbance that produces CD activity is limited to only the complex. Any absorbance by uncomplexed host or any residual chirality on the uncomplexed analyte is not detected and are therefore not interfering. Because these are equilibrium reactions, the correlation between the experimental ellipticity and the analyte concentration is nonlinear. An elegant and simple illustration of the capabilities of this kind of procedure is the determination of cholesterol in human gallstones in which association between the chiral cholesterol and colored bilirubin produced the CD-active complex (Fig. 7) (20, 50, 58, 59). Analogous reactions could be exploited for other naturally occurring pigments.

Other colored host molecules with obvious potential as reversible derivatizing agents are organic dyes and metal

complexes of the first-row transition metals (26). Dyes, of course, are inherently strong absorbers, whereas transition metal complexes are not; however, the CD signals for the complexes are of similar intensities. Dyes are used as prosthetic binding groups in the CD analysis of peptides, proteins, and oligo- and polysaccharides, although more often, the object of the study is to discover stereochemical information about macromolecular structures in solution and at binding sites (6, 60). Their applications as hosts for the chemical analysis of simple molecules, oligopeptides, and nucleic acids using CD detection will ultimately follow.

An example of a colored metal complex as an analytical prosthetic reagent is alkaline Cu(II)-tartrate, which is used routinely for the determination of total-plasma protein. Detection is by absorbance. If racemic tartrate is replaced by the L-Enantiomer, the analytical reagent itself is CD-active. Exchanges of analyte ligands with the L-Tartrate induce significant changes from the CD spectrum of the host complex—changes that can be used not only for structural information about interactions occurring between the ligands in the first coordination sphere, but also as an analytical method selective toward the incoming ligand (26, 61, 62). The assay is a take-off from the analytical discrimination between neomycin B and neomycin C using ORD detection (26). The discrimination power of CD detection allied with the ligand exchange reaction on copper-L-tartrate was demonstrated for the amikacin, gentamycin, kanamycin, neomycin, and streptomycin antibiotics (26) (Fig. 8). The same host complex used to measure enantiomeric excesses or ratios (61, 62) in difficult-to-measure compositional ranges is addressed below.

Fig. 7 Extrinsic (induced) CD spectrum for the complex formed between cholesterol and bilirubin in chloroform solution.

Fig. 8 CD spectra for (a) the chiral Cu(II)-L-tartrate metal complex and for mixed complexes of this host with equimolar amounts of (b) kanamycin, (c) amikacin, (d) gentamycin, and (e) streptomycin.

The choice of an irreversible color-induction reaction requires more ingenuity and greater care in execution. If the extended molecular unsaturation required to produce the color is too exhaustive, the chiral centers could be systematically eliminated, and must be avoided. Reaction conditions are much more unfavorable. Reagents are generally toxic and corrosive, and reaction conditions are anhydrous, e.g., the measurement of plasma cholesterol using a modified Chugaev reagent (63).

SUBSTRATES MADE CD-ACTIVE BY CHIRALITY INDUCTION

Although the heading implies that the analyte is achiral, it does not have to be. Greater analytical selectivity can be engendered by specific mutual influences of intrinsic and extrinsic chirality properties. Chirality induction reactions are generally reversible. Many are used extensively in chiral liquid chromatography (12). Developments presented here are the changes toward chiroptical detection and the applications of direct spectral measurements. Optimal conditions are achieved when chirality resides only on the derivatizing agent, and the chromophore is limited to the analyte. On reaction, the CD activity is exclusive to the molecular complex. Potential interferences from host and guest are inconsequential. The best hosts are linear and cyclic forms of oligo- and polysaccharides, such as the oligomaltoses and the cyclodextrins, which absorb only in the far-UV. Oligomaltoses are more soluble but less selective than are cyclodextrins. Virtually any material that has been used as a stationary phase in chiral chromatography is a candidate for direct homogeneous association reactions, and many others will ultimately appear, e.g., cryptands, vesicles, micelles, peptides, proteins, enzymes, antibodies, and nucleic acids.

Complexation is an equilibrium process. It is recommended that the host molecule be kept in large compositional excess over the analyte, thereby maximizing the mass-action effect and complexing as much of the analyte as possible. The larger the formation constant, the straighter the correlation line between the experimental ellipticity ΔA and the analyte concentration. The β - and γ -Cyclodextrins were used in exploratory investigations as analytical reagents (64) and to determine achiral forms of barbiturates (65), phenethylamines (64), benzodiazepin-2-ones (66), and phencyclidine and its analogs (5). Initial assays were done on prepared laboratory mixtures, but successful assays were also reported for secobarbital in secondal suppositories, meperidine in demerol dispensary

products, and diazepam and flurazepam in pharmaceutical preparations (66).

The CD spectra for chiral complexes, formed by chirality induction on organic dyes by oligomaltoses and oligocelluloses, were used to elucidate the rotational direction of the helical structures of the hosts in aqueous media (60). CD spectra of chiral derivatives formed by the association of aromatic residues, such as 9-Anthroate and p-Hydroxycinnamate with analogous oligosaccharides, were used to probe the local stereochemistry of the ring linkages and conformational arrangements of adjacent groups in acyclic polyols (26).

Protein hosts, whose absorbance and CD spectra are dominated by intense signals in the far-UV range (190–230 nm) are appropriate choices for introducing chirality into any molecule that absorbs at longer wavelengths, e.g., associative complexations of proteins, enzymes, and/or oligopeptides with warfarin (50); bilirubin and its analogs (26, 50, 58, 59); and a few dye molecules (63). Beside the generation of analytical data, structural modifications at the active sites can be monitored over two spectral ranges: the far-UV, where the active group is the peptide bond, and the near-UV, where the absorber is the guest molecule. In addition, CD ought to be seriously considered as an alternative detector for immunoassays because the experimental selectivity might overcome some of the limitations associated with polyclonal antibodies.

DETERMINATION OF ENANTIOMERIC EXCESS IN PARTIAL RACEMIC MIXTURES

For all types of chemical analysis, the quality of the results ultimately relates to the chemical purity of the best available SRM. For naturally chiral substances, there is the additional more serious concern over what constitutes absolute enantiomeric purity. Not even mass spectroscopy, which provides assurance that a substance is chemically pure, can be used to report absolute enantiomeric purities. To actually report an enantiomeric purity higher than 99% is truly beyond the capability of current analytical methodology (20). As noted previously, the fact is that results are measured relative to an enantiopurity defined to be 100%. Chemical purities aside, the measurement of enantiomeric purity and enantiomeric excess is technically the same, the difference being the extent of racemization. There are only two experimental options, either enantiomeric separations or multivariate spectroscopic analyses, that involve either two distinct detectors or multiple-wavelength detection for a single detector, as noted above.

The newly described derivatization reactions fulfill the second option.

If the chosen derivatization reaction is chirality induction, a simple two-step process is to measure the CD spectrum for the underivatized partial racemic mixture, followed by a measure of the net spectrum after the addition of the derivatizing agent to the mixture. Fundamentally, the reaction is the simple competitive instantaneous complexation of the enantiomers with, for example, β -Cyclodextrin, in which two diastereoisomers are formed. These might have different formation constants, or different induced spectra, or both. Regardless, the result is a change in the original CD spectrum. The two unknown enantiomeric concentrations are calculated by solving the simultaneous equations that describe the additivity of the two enantiomers in the case of the original solution and the two diastereoisomers in the case of the derivatized solution. The method was used with limited success in the measurement of enantiomeric distribution for prepared nonracemic mixtures of R- and S-Nicotine (26). The poor results could in part be attributed to the spectral changes being very small.

More accurate results were achieved by exchanging both the enantiomers in prepared nonracemic mixtures of ephedrine and pseudoephedrine with the coordinated L-Tartrate ligand of the Cu(II)-L-Tartrate host complex dissolved in 0.10 M aqueous base (62). The first CD spectrum is that for the parent complex and the second for the mixed ligand complexes, where only one of the two bonded L-Tartrate ligands on Cu(II) is exchanged by either the (+)- or the (–)-ephedrine or pseudoephedrine enantiomers. The total signal is the sum of three terms, the CD signal from the decreased concentration of the parent complex, plus the CD signal from the 1:1 complex of Cu(II) with one L-tartrate and the (+) enantiomer, plus the CD signal from the 1:1 complex of Cu(II) with one L-Tartrate and the (–) enantiomer. With careful control of the reaction conditions, the detection limit for the enantiomeric purity was on the order of $\pm 2\%$. In fact, changes in the CD signal on complexation was so large that almost equivalent results were more easily obtained using polarimetric measurements at only four wavelengths.

CD DETECTION/LIGAND EXCHANGE FOR ASSAYS OF PEPTIDES, OLIGOPEPTIDES, AND PROTEINS

With literally thousands of potential new drug substances in the combinatorial chemistry pipeline and the expanding emphasis on chiral drugs, the development of low-cost,

routine quality-control procedures is becoming a priority in pharmaceuticals and biotechnology. Ligand-exchange derivatization, coupled to CD detection, has the potential to do that for peptides, oligopeptides, and proteins.

Regulatory agencies have already set the standards for quality control (QC) for chiral drug substances. If it is a company's decision to market a chiral drug as a single enantiomer (the eutomer), the submission for regulatory approval must also include the equivalent chirality information for the other, nontherapeutic enantiomeric form (the distomer). An accurate determination of the enantiomeric purity of both forms is essential. Furthermore, chemical racemization will alter the eutomer to distomer ratio with time, diminishing the therapeutic property of the eutomer. Another very significant factor in QC, therefore, is to be able to accurately measure the rate of change of enantiomeric purity and decide when the meaningful therapeutic value of the eutomer has expired.

By replacing the L-tartrate ligand of the Cu(II)-derivatizing agent described above with D-histidine, a very selective host complex for ligand exchange was created (67–71). Much of the analytical selectivity accomplished by full spectrum visible-range CD detection is attributable to the specifics of the ligand–ligand interactions that ostensibly occur within the first coordination sphere of the complex. The extent of the selectivity that is accomplished for peptides and proteins is extraordinarily high (Fig. 9).

It was also determined that the CD spectral changes are extremely sensitive to changes in the amino acid sequence among residues that are far removed from the binding sites. A case in point is the individualized CD spectral changes for the exchange of D-histidine with human, human LysPro, porcine, and bovine insulin forms, all of which are 51 amino acid residue proteins

Fig. 9 CD spectra for the host Cu(II)-D-histidine spectrum and the mixed complexes with a series of tripeptides.

Fig. 10 CD spectra for (A) the Cu(II)-D-histidine host complex and for the mixed ligand complexes with (B) bovine insulin, (C) human insulin, (D) porcine insulin, and (E) human LysPro insulin.

(70). It is a known fact that proteins bind to Cu(II) ion in aqueous base by first substitution via the *N*-atom at the amine terminus (72). Chelation is completed by second and third substitutions into the metal first coordination sphere through the *N*-atoms of the first and second peptide functional groups. Because all four insulins have identical initial sequences, the observed CD spectral changes on ligand exchange are caused by some other structural variations. The only differences in the insulin residue sequences occur either at or adjacent to the acid terminus of the B-chain. Human insulin differs from human LysPro by the simple exchange of lysine and proline residues at positions B-28 and B-29. Porcine and human insulins differ by one residue, alanine for threonine, at position B-30 (70). The only explanation that accounts for this is that the metal ion is enclosed by an extensive, flexible, chiral, three-dimensional architecture and that subtle differences in the conformational properties of the enclosure bring different residues into the realm of the ligand to metal ion electronic transitions. With the D-Histidine kept in very large excess over the insulin analytes, there is a good quantitative linear correlation of the CD signal with concentration. What many researchers may have failed to realize in drug modeling is that when two chiral molecules interact, the stereochemical conformations of both change, and these changes may be just as significant in the mechanism of drug action as the absolute conformations of the participants themselves.

In other tests of the ligand exchange/CD detection assay procedure, it was demonstrated that 51 of a total of 53 di- and tripeptides could be uniquely identified by the character of the changes in the CD spectra for the mixed

Cu(II)-peptide-D-histidine complexes (67, 68, 70). A series of 19 neuropeptides was the focus of another investigation (69, 71). Neuropeptides are invariably chiral molecules and, because of the peptide bond, are CD-active. Once again, all but two of the analogs were individually distinguishable by the CD spectra for the mixed ligand complexes. For the two exceptions, ICI 174,864 and PLO17, the terminal amine group is substituted and, as such, it is not competitive with D-histidine in binding to the Cu(II) ion. In other words, substitution did not occur. To determine whether the CD spectra had characteristic properties that could be associated with the structure of first coordination spheres of the metal complexes, a Y-correlation matrix of the CD data was subjected to principal component analysis (PCA). All of the spectra can be accounted for mathematically by only four factors (71). The spectral data for each neuropeptide analyte can be graphically represented by a single point in an X-Y plot of the first two principal components, PC1 and PC2. When the points are subjected to a hierarchical clustering algorithm, the neuropeptides

Fig. 11 Cluster plot of the first and second principal components derived by PCA from spectral data. The δ -receptor cluster covers (1) DTLET, (2) DSLET, (3) DADLE, (4) α^2 -Leu⁵-enkephalin, and (5) DPDPE. The μ -receptor cluster includes (6) DAGO, (7) Met⁵-enkephalin, and β -endorphin. The alternate δ -receptor cluster is composed of (9) Leu⁵-enkephalin and (10) Leu⁵-enkephalin amide. The κ -cluster of the dynorphins contains (11) B(1-13), (12) A(1-13); (13) A(1-9); (14) A(1-11); and (15) A(1-13) amide. No receptor preference was reported for PLO 17 or ICI 174 864.

are observed to aggregate according to their preferences for the δ , μ , or κ protein receptors (Fig. 11). This calibration model has the potential to become a prototypical-predictive in vitro model for correlating CD spectroscopic data with quantitative structure-activity relationships (QSAR) and, on further substantiation, may become a viable procedure for new drug forms (71). Despite the fact that the system is a mixed equilibrium reaction, in quantitative terms, a strong linear correlation exists between PC1 and analyte concentrations.

A recurring chiral property in many of the neuropeptides is the presence of at least one D-enantiomeric residue, e.g., natural and designer enkephalins such as DALDA, DAGO, and DPDPE. Locating the position of the D-form in a sequence is a challenging endeavor that is being systematically studied on two series of model penta- and hexapeptides. The role of D-enantiomeric forms in biotechnology drug substances is a very real interest and more especially in view of the recent recognition of the existence of D-Serine, which functions as neurotransmitter in mammalian brain tissue (73). The D-Enantiomer is synthesized in the brain from the natural L-Form catalyzed by serine racemase.

SUMMARY

The intent of this article was to demonstrate, based on a wealth of relatively new experimental data, that there is sufficient analytical selectivity and sensitivity to accept polarimetry and CD as viable and easy-to-use analytical detection methods. In contrast to other detectors, they provide the capability of making direct analytical assays after a sample work-up that is a simple solvent extraction and of measuring enantiomeric purities in the ranges specified by the FDA for the process and quality control for new chiral drug substances. In the future, broader applications will be developed, especially as the current analytical emphasis turns toward nucleic acid protein interactions and the CD properties of intact single cells.

CARCINOGENICITY TESTING: PAST, PRESENT, AND FUTURE

Koen Van Deun

Janssen Pharmaceutica N.V., Beerse, Belgium

INTRODUCTION

This chapter presents an historical overview of cancer, carcinogenicity testing, and human cancer causes. Cancer has been known for a very long time, but the awareness of human carcinogenicity caused by chemicals is a phenomenon of the 20th century. This in turn has produced legislation that prohibits the use of carcinogens in the food chain and has provided guidelines for carcinogenicity testing in animals. Lifetime studies (18–24 months) in two main rodent species (rat and mouse), also known as the “Standard Chronic Bioassay,” have been conducted since the 1960s.

Meanwhile, various deficiencies have been detected in the Chronic Bioassay; over-sensitivity is the major one. Hundreds of compounds have been tested with the Chronic Bioassay method, and about 50% have yielded (false) positive results. Lack of relevance to man has often been demonstrated by additional mechanistic studies. Additionally, more mechanistic and molecular knowledge has been gained in regards to the human carcinogenicity concept, including genotoxic versus epigenetic carcinogens, the multi-stage cancer theory, and human life style factors involved in carcinogenesis.

The above evolutions have opened up new opportunities for carcinogenicity testing, including short-term alternative carcinogenicity models. In addition, carcinogenicity testing is evolving from a standard chronic bioassay to a weight-of-evidence approach, where the mechanisms involved in rodent and human carcinogenesis are considered, and where communication between industry and regulatory authorities is encouraged.

CARCINOGENICITY TESTING IN THE PAST

History of Cancer, Carcinogenicity Testing, and Human Causes of Cancer

Cancer has probably existed as long as multicellular organisms have. Paleontologists have shown the presence of tumors in the bones of dinosaurs, long before the advent of *Homo sapiens*. The Ancient Egyptians knew of the

existence of cancer in man. A papyrus with a hieroglyph that shows a clinical tumor was discovered. Autopsies of mummies have shown bone tumors in Egyptians. The first real descriptions of various tumors were those presented by Hippocrates in the 4th century B.C. He used the term “*carcinoma*,” by which he meant a tumor that spreads and kills the patient. In the 1st century B.C., Galen made the distinction between “*natural tumors*,” such as those present during the development of breasts in female adolescence and “*tumors, which go beyond the bounds of nature*,” such as those related to bone healing following a fracture. Finally, he described “*unnatural tumors*,” which today can be defined as a “neoplastic” growth of tissue. The views of Hippocrates and Galen dominated medicine for many centuries. In the 19th century, cancer knowledge expanded enormously, primarily through intensified studies on anatomy and histology. Bichat, and later Müller, confirmed Galen’s theory. They postulated the hypothesis that cancer arises from accidental tissue formation. This in turn prompted Pasteur to propose his theory of “*omnis cellula et cellula*.” Every cell originates from another cell.

The discovery that exposure to exogenous chemicals could lead to cancer in humans was first made in the late 18th century, when Percival Pott demonstrated the relationship between cancer of the scrotum and the occupation of chimney sweepers exposed to coal tar/soot. Other examples noted later were scrotal cancers in cotton spinners exposed to unrefined mineral oils, and cancers of the urinary bladder in men who worked in textile dye and rubber industries due to their exposure to certain aromatic amines used as antioxidants. Experimental induction of cancer by chemicals was first reported in detail by Yamagiwa and Ichikawa in 1918, when repeated application of coal tar to the ear of rabbits resulted in skin carcinomas. Over the next few years, Kennaway and Leitch confirmed this finding and demonstrated similar effects in mice and rabbits from the application of soot extracts, other types of tar (e.g., acetylene or isoprene), and some heated mineral oils. These researchers also observed skin “irritation” sometimes accompanied by ulcers at the site of application of the test material. “Irritation” was thought to be an important factor in skin tumor development. However, not all irritants (e.g., acridine) induced skin cancer in mice and conversely, some purified

chemicals isolated from these crude materials produced a high incidence of skin tumors with little or no irritation. These observations suggested that intracellular changes induced by carcinogens might lead to cancer, independent of any lesions observable visually or by light microscopy. As a result, the hypothesis that cancer stems from the interaction of a chemical with a “sensitive” site in the cell was proposed. Further reading on the early history and concepts in cancer is provided by Van Cauteren et al. (1), Roe (2), and Grasso et al. (3).

By the mid 20th century, causes of human cancer related to exposure of chemical substances was of growing concern. Until the 1950s, the known causes of cancer were those associated with chemical exposure at the work place. These findings led to the concept that most human cancers were caused by environmental chemicals. For example, Hueper noted that the increasing rate of lung cancer coincided with the remarkable growth of industry and motorized transportation, as well as the use of industrial carcinogenic products and their release as effluents and exhausts into the occupational and general atmosphere. However, Wynder and Doll later showed that a major type of cancer, lung cancer, which was increasing sharply in men, was due to the chronic use of cigarettes and exposure to tobacco smoke.

One of the first indications that factors other than chemical interaction with specific intracellular sites could be responsible for tumor induction was the discovery of fibrosarcomas, observed around large bakelite discs implanted subcutaneously in rats. A similar observation was seen after wrapping pieces of cellophane film around the kidneys in rats. After several months, a large tumor developed around the cellophane film in some of the rats. The finding of “solid-state” carcinogenesis was confirmed later in the 1960s by implantation of various solids (including noble metals such as gold, silver, or platinum), which led to the development of sarcomas. The shape, and particularly the size of the implant, had a determining influence on sarcoma induction. In addition, iron-dextran was found to produce this type of tumor following repeated subcutaneous injections in rats and mice. Subsequent investigations revealed that some food colorings evoked local sarcomas in rats and mice after repeated subcutaneous administration. The principal mechanism believed to be involved in sarcoma induction was the continued activation of reparative processes in connective tissues by the physical, tissue-damaging properties. Further examples of chemical and solid-state carcinogenesis that lead to tumor development in rodents are provided by Grasso et al. (3) and Weissburger (4). Other recent evolutions in carcinogenicity concepts will be described further in this review.

History of Carcinogenicity Testing Legislation

One area of great contemporary concern was the entry of carcinogens into the human environment through food in the form of food additives and food contaminants, such as pesticides. Thus, hearings were held before the U.S. Congress relative to desirable modifications of the pure Food and Drug Laws that had been part of legislation since 1908. In 1958 and 1960, Congressman Delaney introduced the following two pieces of legislation, also known as the “Delaney Clause:”

1. Food Additives Amendment of 1958: Federal Food, Drug and Cosmetic Act. Section 409(c) (3) (A): “. . . no additive shall be deemed to be safe if it is found to induce cancer when ingested by man or animal, or if it is found, after tests which are appropriate for the evaluation of the safety of food additives, to induce cancer in man or animal. . . .”
2. Color Additive Amendment of 1960; Federal Food, Drug and Cosmetic Act. Section 706 (b) (5) (B): “A color additive that will result in ingestion shall be deemed unsafe, and shall not be listed, . . . if, after tests which are appropriate for the evaluation of the safety of additives for such use or after other relevant exposure of man or animal to such additive; it is found by the Secretary to induce cancer in man or animal.”

This legislation consisted of the absolute prohibition of entry of “carcinogens” into the food chain, and established for the first time the view that any substance that could be considered carcinogenic was not to be added to foods or cosmetics. There was no room for quantification and calculation of risk. More detailed information on this clause can be found in the article by Weissburger (4).

From 1961 onward, the “Bioassay Program” of the National Cancer Institute (NCI) was developed. This program was based upon the need for a more systematic investigation of chemical carcinogenesis in animals (rats and mice). Each test also involved the use of appropriate negative and positive control carcinogens to verify that the models actually gave the appropriate results. Preliminary toxicology testing was performed using five rats or mice per group, and applying the dosage for 6 weeks, with a further holding period of 2 weeks without chemical administration to detect delayed toxicity. Animals that survived provided information on survival and weight gain (loss), the highest possible dose, and the maximum tolerated dose (MTD). The final NCI Chronic Bioassay consisted of a life-time (18–24 month) oral administration to rats and mice up to the MTD, with a second group at 50 or 30% of the selected MTD. The principle of the MTD was chosen since a number of bioassays in the literature

with the known human carcinogens gave a good incidence of cancer only at high dose levels. Between the 1960s and the 1980s, the NCI Bioassay Program tested many types of chemicals that humans were potentially exposed to, including chemicals used in cancer chemotherapy, hair dye formulations, and a series of agricultural chemicals, including pesticides, insecticides, and fungicides.

The NCI Chronic Bioassay became the basis for current guidelines on carcinogenicity testing. Protocols and reports for the large-scale bioassays were standardized in order to increase scientific acceptability.

A number of the chemicals administered were found to induce cancer in rats and mice. Some chemicals, particularly agricultural products, were negative in the rat models but induced liver tumors in mice. With either type of response, a chemical that induced cancer in any test was labeled a carcinogen, and by extrapolation was considered to be a human cancer risk without questioning its relevance or the underlying mechanism.

Towards the end of the 1980s, the NCI carcinogenesis branch merged with other agencies that shared similar efforts to form the National Toxicology Program (NTP). The NTP placed much more emphasis on mutagenicity and other short-term tests, teratology, behavioral effects, neurotoxicity, and various subchronic studies.

More information on the history of the Chronic Bioassay can be found in the reviews by Weissburger and Weissburger (5, 6).

Carcinogenicity Testing Guidelines

In the 1970s and 1980s, the US, European, and Japanese Registration Authorities established guidelines for carcinogenicity testing in animals for the various chemicals

characterized by possible long-term intake by man. These chemicals included food and color additives, agrochemicals, industrial chemicals, solvents, human pharmaceuticals, and veterinary products. The guidelines were based upon the Chronic Bioassay of the NTP and gave indications for route and frequency of dosing, dose levels, group sizes, duration of the study, and observations during the study. A summary of the various guidelines is provided in Table 1. More detailed information on the various guidelines is provided by an overview of Inveresk Research International (7). Meanwhile newer versions of most of the guidelines have become effective.

CURRENT CARCINOGENICITY TESTING

A description of the standard approaches in carcinogenicity testing for the safety of chemicals is provided.

Standard Rodent Chronic Bioassay

Species and strains

According to the previously described guidelines, carcinogenicity studies have to be performed in two rodent species, usually the rat and the mouse. Ideally, the strains should have a low spontaneous incidence of cancer, but they should also be sensitive to induction of cancer by human carcinogens. Commonly used species are the Sprague Dawley, Fisher F344, or Wistar strains in rats, and the CD-1 or C57BL-based strains in mice. At least 50 animals are included per sex in each dose group. Today, at least three dose groups are used as well as at least one

Table 1 Establishment of guidelines for carcinogenicity testing in animals

Continent	Scope	Authority, year of approval
General	Chemicals	OECD, 1981
US	Food and color additives	FDA, 1982
	Agrochemicals	EPA–FIFRA, 1984
	Chemicals	EPA–TSCA, 1985
EC	Pharmaceuticals	EC directives, 1983
	Chemicals	EC directives, 1988
Japan	Agrochemicals	MAFF, 1985
	Veterinary products	MAFF, 1988
	Pharmaceuticals	MHW, 1989

EPA: Environmental Protection Agency; FDA: Food and Drug Administration; FIFRA: Federal Insecticide Fungicide and Rodenticide Act; MAFF: Ministry Agricultural Forestry and Fisheries; MHW: Ministry for Health and Welfare; OECD: Organisation for Economic Co-Operation and Development; TSCA: Toxic Substances Control Act.

negative control group, which results in minimally 200 males and 200 females for one study.

Doses and route of administration

The animals are exposed daily to the test compound from the age of 6 weeks onward. The administration procedure should simulate human exposure as closely as possible; oral intake is the most common route.

In the past, the test item was often mixed in the drinking water or the feed, either in a fixed concentration in the feed during the entire study or with regular adaptations to maintain a steady ratio of mg/kg of body weight intake during the entire life expectancy. Nowadays, oral gavage administration in the stomach is used, except for agrochemicals and food additives, where feed administration is still applicable. Oral gavage administration provides more certainty of test item intake, but also leads to another pattern of test item exposure in the body (peak concentrations after dosing). Dose-selection for the various dose groups has been based mainly upon a MTD, which is defined to elicit slight target organ toxicity but will not shorten the treated animals' survivability from any toxic effects other than the induction of neoplasms. For the most part, a body weight gain loss of 10% is considered acceptable as evidence of minimal toxicity. The medium dose may elicit minimal toxicity; however, the low dose should be free of any toxicity.

The MTD is mostly defined in a 3-month dose-range-finding study, allowing optimal dose setting for the pivotal chronic bioassay.

Duration

The studies are designed to last for at least 24 months and survival should be at least 25 animals per sex in the control and low dose groups, both in males and females. In the past, the studies were often extended beyond 24 months because survival (especially in the control and low dose group) was still above 25 animals/group/sex, and because of concern that the carcinogenic effect might become visible only at a later end point. Currently, most of the studies are not extended since geriatric pathology increases, which can complicate and obscure the assessment of carcinogenicity.

Experimental conditions

Experimental conditions are of utmost importance because they can influence the results of the study. Factors such as hygiene, temperature, relative humidity, number of air replacements, and light have to be maintained and monitored consistently during the study.

Today, carcinogenicity studies are performed under Specific Pathogen Free (SPF) conditions. This means

that SPF animals are obtained from commercial breeders and are placed in SPF rooms after arrival in the experimental unit. Other factors taken into account are quarantine, health monitoring, and hygienic measures during handling, such as sterile gloves and mouth masks. Good Laboratory Practice (GLP) has also contributed to improved test conditions. GLP not only applies to the way animals are handled, but also to appropriate documentation and recording of all actions during a study. This leads to better traceability, reconstruction, and interpretation of study data and results. All the improvements in experimental conditions have led to increased survivability in the animals. In the past, various deaths occurred due to respiratory or other infectious diseases; these are almost totally excluded within the current improved health condition of the animals.

Parameters examined in the study

During the 24-month study, various study parameters are examined as shown in Table 2. The daily follow-up is of utmost importance in order to pick up unexpected findings. If problems arise, the study director's, veterinarian's, or pathologist's attention is drawn, and immediate and appropriate actions are requested. After necropsy during or at the end of the study, a mean list of 30 tissues is sampled and examined macroscopically. This may lead to a total number of 12,000 or more tissue samples for a single carcinogenicity study. All tissues are fixed and processed for further microscopic examination for neoplastic and nonneoplastic changes. These examinations are done by pathologists specialized in rodent pathology. The final aim is to detect the number of animals with tumors, but also multiplicity of tumors and whether the tumors caused death of the animal.

Histopathological evaluation

As indicated in Table 2, histopathological examination is performed on all animals to detect "nonneoplastic" and especially "neoplastic" changes induced by the test compound. Nonneoplastic changes may include inflammatory, degenerative, or other changes in various tissues, either caused by the test item or by geriatric pathology. Neoplastic changes, or tumors, can be divided by "benign" and "malignant" neoplasms. Benign neoplasms are well defined, often encapsulated, noninvasive, and well differentiated. They grow relative slowly, display relative few mitoses, and are not metastatic. Malignant tumors are less well defined and usually not well encapsulated. They are invasive and relatively undifferentiated; they grow rapidly, display abundant mitosis, and finally undergo metastasis).

Table 2 Parameters and frequency of observation or measurement in carcinogenicity studies

Frequency	Parameter	Examples of intended endpoint(s)
Daily	Mortality	Week of death or sacrifice Death or sacrifice status: Natural death or sacrificed in bad condition Terminal sacrifice
	Clinical observations	Drug-related signs of toxicity Bad condition, preceding mortality
Weekly	Body weight & weight gain	Drug-related body weight and weight gain or loss (10–15% body weight gain loss is accepted at MTD)
	Food consumption	Drug-related changes in food intake
After 6 or 12 months	Toxicokinetics	Exposure of parent compound and metabolites and relation to human exposure
After 6, 12, 18 months and terminally	Hematology	Drug-related haematological deviations
	Clinical biochemistry	Drug-related biochemical deviations
Terminally (also on all animals dying or sacrificed during the study except organ weights)	Gross pathology	Drug-related macroscopic findings
	Organ weights	Drug-related organ weight changes
	Histopathology	Nonneoplastic changes (including “pre-neoplastic” changes, such as hyperplasia) Neoplastic changes (tumors) Malignancy status (malignant or benign) Cause of death (tumors that caused death = probably fatal and fatal tumors; tumors that did not cause death = probably incidental and incidental tumors, and tumors in terminally sacrificed animals) Multiplicity of tumors (number of tumors/animal and/tissue)

Preceding conditions to neoplasia, such as “hyperplasia,” (which refers to an increase in the number of cells) and “hypertrophy,” (which refers to an increase in cell dimensions), can also be found.

Histopathological examination is a very intensive job; months may go by before all tissues are evaluated.

In addition, the histopathologist will relate the histopathological findings with the other nonmorphological findings during the study, such as hematological or biochemical results, either for individual animals or for dosed groups. As such, diagnoses and mechanisms for the findings are established. For the most part, independent pathologists

perform peer reviews in order to have confirmation on the exact diagnosis or mechanism.

Historical control data

Historical control data can be used to interpret the changes seen in carcinogenicity data. These control data can apply to the various parameters studied, such as hematology, biochemistry, and the incidences of tumors. They may be used when differences are seen between the incidences of tumors in the dosed groups and spontaneous incidences in concurrent control animals, where coincidence is suspected, or for tumors with very sporadic incidences.

Spontaneous incidences in tumors are commonly seen in untreated rats and mice, and vary from strain to strain. Examples include pituitary and mammary tumors in rats, and liver and lung tumors in mice. The incidences of tumors can vary, and even today, there is no clear understanding of their etiology, except for ad-libitum feeding. On the other hand, caloric restriction could retard aging (associated with a reduction in the rate of cell replication), and reduce the incidence of degenerative diseases and tumor incidences (2).

Statistical analysis

Statistical analysis is performed on all parameters in the study. Its most fundamental objective is to determine whether administration of the test agent results in an increase in tumor incidence rates as compared to those in unexposed controls. Various statistical methods can be used. Tests for increased tumor occurrence rates between dosages may be based on "pair-wise comparisons," such as the Chi-square test for 2×2 tables, the Fisher's exact test, or the Cochran-Armitage test. These tests are most appropriate when survival rates do not differ appreciably in the various dose groups.

If the treatment results in reduced survival, early mortality in the high-dose groups may preclude the development of tumors and other statistical methods are required. Peto proposed a test for differences in tumor occurrence rates due to treatment, taking into account differences in survival and the times at which tumors were observed. This procedure requires information on the cause of death of each animal, and is based on a time-stratified contingency table analysis of the prevalence of incidental tumors that did not kill their host and a similar analysis of fatal tumors that resulted in death prior to the study. These two analyses are then combined to arrive at an overall test for increase in trend in tumor occurrence rates allowing for differential survival rates among the treatment groups. More information on study design and statistical analysis is

provided by Feron et al. (8), Portier (9), Gart et al. (10), and Ciminera and Allen (11).

Cancer Risk Assessment

Once carcinogenicity testing has been performed, carcinogenicity risk assessment must be performed. Regulatory agencies have the responsibility to identify and assess compounds that are administered in food, provided as pharmaceuticals, or have the potential to be released in the environment at levels that warrant concern. Various topics have to be addressed when characterizing the carcinogenic risk. These include hazard identification (i.e., the likelihood to be a human carcinogen), dose-response, and extent of human exposure. Each of these assessments involve the use of many assumptions and estimations, the magnitude of which may be decreased by the incorporation of more information (e.g., mechanistic studies, pharmacokinetic data, and improved low dose extrapolation models). Velasquez et al. (12) have provided an overview of cancer risk assessment by the US Environmental Protection Agency (EPA) and biological issues in cancer risk assessment. In addition, the International Agency for Cancer Research (IARC) has evaluated and published carcinogenic risk to humans for hundreds of chemicals (13, 14).

In both systems, chemicals, including pharmaceuticals, are assigned to five groups: 1) carcinogenic to humans; 2) probably carcinogenic to humans; 3) possibly carcinogenic to humans; 4) not classifiable for human carcinogenicity; and 5) probably not carcinogenic to humans. Assignment to one of these groups is based on scientific judgement of data derived from studies in humans and animals as well as supporting data. Data are estimated as providing sufficient, limited, or inadequate evidence for carcinogenicity in humans and rodents.

For example, agents assigned as probably carcinogenic to humans have shown a positive association between exposure and human cancer, and have also shown sufficient evidence of carcinogenicity in animals. For the possible human carcinogens, only sufficient evidence for carcinogenicity in animals is established, but inadequate or no data in humans.

Evolution in Carcinogenicity Testing and Concepts Between 1960 and 2000

Mechanistic knowledge of carcinogenicity has increased enormously since the introduction of the Standard Chronic Bioassay. First, "genotoxic" carcinogens were distinguished from "nongenotoxic" carcinogens, which

Table 3 Main classification of chemical carcinogens

Category	Classification (+ example)	Features
Genotoxic	DNA-alkylating	Transspecies occurrence
	activation-independent (mustard gas)	At low dose levels
Epigenetic	activation-dependent (nitrosamines)	Short latency period
	Interfering with DNA (inorganic metals)	No threshold for extrapolation to humans
	Promoters (phenobarbital)	Mostly in one species, strain or sex
	Cytotoxic/mitogenic agents (<i>d</i> -limonene, saccharin)	At high dose levels (MTD)
	Hormone-modifiers (estrogen)	Long latency period
	Immunosuppressors (cyclophosphamide)	Threshold considerable for extrapolation to humans
	Peroxisome proliferators (clofibrate)	
	Receptor-mediated (dioxins)	
	Miscellaneous mechanisms (sodium nitrilotriacetic acid)	

led to a separate test battery for genotoxicity testing. Second, a “multistage” concept in carcinogenesis was discovered up to a molecular level. Third, “lifestyle factors” were found to play a major role in human cancer causes.

Genotoxic vs. nongenotoxic carcinogens

During the 1970s, Ames postulated that most human carcinogens were “genotoxic.” Genotoxic compounds may react, either directly or indirectly (after metabolic activation) with DNA, which leads to alteration of the genetic material, and mostly to carcinogenicity in rodents and humans. On the other hand, many rodent carcinogens are “nongenotoxic” or “epigenetic,” and act through a different mechanism.

The knowledge of these two basic mechanisms in carcinogenicity has led to the current classification of chemical carcinogens in “genotoxic carcinogens” and “nongenotoxic” or “epigenetic carcinogens.” The second category comprises agents that exert primary cellular effects, which further result in carcinogenicity in rodents (“rodent carcinogens”). Genotoxic and nongenotoxic carcinogens, each with their own typical features, are further classified in main categories, as shown in Table 3. An example of an epigenetic rodent carcinogen is the artificial sweetener saccharin. In the past, when saccharin was shown to produce bladder tumors in rats, it was considered to be a likely (possible) human carcinogen. Today, it has been removed from the list of suspected human carcinogens since a large body of experimental data indicates that the rat bladder tumors arise from mechanisms that are not relevant to the human situation, which in turn supports the conclusion that saccharin is not related to bladder cancer in humans. Phenobarbital, a sedative, is an example of an agent that extensively

induces drug-metabolizing enzymes in rodents. This results in liver tumors, but also in enhanced catabolism of thyroid hormones by the liver enzymes, which leads to thyroid stimulation by compensatory mechanisms and further to thyroid hypertrophy and hyperplasia, and eventually to thyroid tumors. Epidemiological studies, however, have indicated that it is of no concern for humans. More detailed explanations and examples of epigenetic carcinogens have been published by Purchase (15), Shaw and Jones (16), Van Cauteren et al. (17), and Williams and Whysner (18).

Due to the increase in knowledge of genotoxic and nongenotoxic mechanisms, test batteries were designed to evaluate “genotoxicity” in the early phases of drug development and prior to the start of chronic bioassays. These assays varied from test systems such as bacteria, yeast cells, and *Drosophila*-flies, to cell cultures of mouse lymphoma cells or human lymphocytes and in vivo systems, such as rodents for exposure of bone marrow. An overview of the genotoxicity toxicity assays that are currently performed for regulatory testing is shown in Table 4.

As indicated in Table 4, the potential to induce gene mutations or chromosome aberrations is investigated in a battery of genotoxicity studies. Additionally, DNA-damage and repair can be investigated separately. For the in vitro assays, some chemicals only become genotoxic after bioactivation to an electrophilic reactant. Therefore, in some in vitro assays, a liver enzymatic fraction is added in order to mimic the normal in vivo metabolic (de)activation route of compounds. The knowledge of the genotoxic versus the nongenotoxic carcinogens and of the mechanism of epigenetic carcinogenesis in rodents has gained significant importance in the extrapolation or relevance to humans. For example, humans have been

Table 4 Overview of genotoxicity assays

Genotoxicity assays	Genetic damage type
Assays according to current ICH-4 Standard battery:	
Ames reversion test in salmonella typhimurium or <i>Escherichia coli</i> (in vitro)	Gene mutations
Chromosomal aberration test in cell culture of human lymphocytes (in vitro) or	Chromosome aberrations
Mouse lymphoma test in mouse lymphoma cells (in vitro)	Chromosome aberrations and gene mutations
Micronucleus test in rodent bone marrow (in vivo)	Chromosome aberrations
Additional assays if cause for concern:	
Unscheduled DNA synthesis (UDS) test in rodent hepatocytes (in vitro/in vivo)	Primary DNA-damage
32P-postlabeling test	Primary DNA-damage
Test with transgenic animals	Gene mutations
Chromosome aberration test in human lymphocytes (in vitro) or in rodent bone marrow (in vivo)	Chromosome aberrations

exposed to many pesticides known to cause cancer in experimental animals by epigenetic mechanisms, but none has been definitely linked to cancer in humans. The absence of effects in humans is usually because exposure is below the threshold for the epigenetic effects. In addition, some cancer mechanisms may be specific to the rodent test animals and not relevant to humans at any possible exposure.

Multistage cancer concept

Armitage and Doll postulated the multistage cancer concept in the 1960s. According to this theory, tumors can arise from single cells that obtain proliferative capacity after several consecutive independent events at cellular level. Cancer of the colon is one of the best-understood examples of multistage carcinogenesis; it reveals at least six stages in its development. Recently, it also has become possible to identify the molecular events that underlie the development of these tumors. Some examples of somatic alterations in this model are gene mutations of a “ras” proto-oncogen, detected in approximately 50%, and loss of a “P 53” tumor suppressor gene in approximately 75% of the colorectal carcinomas. Similar alterations have also been detected in other human tumors, such as lung, breast, and brain tumors. More detailed information and examples of multistage carcinogenesis are provided by Fearon and Vogelstein (19), Couch (20), and Purchase (15). Based on the above theories, the main steps involved in carcinogenesis are: 1) “initiation” (first stimulus leading to alteration of the DNA in the cell nucleus); 2) “promotion” (further expression of the genetic change, leading to benign tumors); and 3) “progression” (further evolution of the tumor leading to malignancy and clinical manifestation).

“Initiation” is the first phase of carcinogenesis whereby cells are exposed to a carcinogenic agent. In this stage, an irrevocable step is taken in which daughter cells may later

acquire relative autonomy with regard to cell division. “Promotion” is the next phase, in which initiated cells, not yet recognizable, are stimulated to divide and become clinically or pathologically detectable neoplasms. “Progression” is the phase in which the tumor increasingly damages the host and finally destroys it. Widespread invasion and metastasis, with destruction of the original normal tissue, are predominant in this phase.

Lifestyle factors

Finally, associated causes of major human cancers have been discovered. Most cancers are associated with lifestyle (specifically tobacco and excessive alcohol use), inappropriate nutritional traditions, and lack of exercise. These lifestyle components involve currently known genotoxic carcinogens, and importantly, nongenotoxic carcinogens. The effect of nongenotoxic carcinogens is highly dose-dependent and also reversible upon lowering the dose below a threshold. Thus, it is quite possible to lower human cancer risk as well as the risk of related chronic diseases, such as coronary heart disease, hypertension and stroke, and adult on-set diabetes, by proper lifestyle adjustments. Clearly, the Delaney Clause (requiring total absence of carcinogens in the food chain) plays no role in disease prevention (5). Misconceptions about the relationship between environmental pollution and human disease, particularly cancer, have also been highlighted by Ames and Gold (21). Smoking, dietary imbalances, chronic infections, and hormonal factors, all influenced by lifestyle, are considered major causes of cancer. Reduction in synthetic pesticides in the food chain does not effectively prevent diet related cancer, whereas high consumption of fruits and vegetables (containing anti-oxidants) does. On the other hand, humans do ingest many natural chemicals (in fruits and plants). Even though only a small proportion has been tested for carcinogenicity, half

of them are rodent carcinogens. Therefore, prevention of cancer will not only be based upon carcinogenicity testing and risk assessment of chemicals, but from knowledge obtained from biomedical research, education of the public, and lifestyle changes (21).

Need for Changes

Deficiencies of the standard chronic bioassay

If clear-cut evidence of genotoxic potential is obtained in the genotoxicity battery, especially via *in vivo* assays, then the potential for carcinogenicity in humans is highly suspected. In that case, drug development is discontinued. For compounds with negative or equivocal results in the genotoxicity battery and positive results in the Standard Chronic Bioassay, interpretation can be difficult.

The concept of the bioassay for detecting carcinogenic potential was developed at a time when relatively few agents were recognized as being carcinogens. However, during the past 20 years, many investigations have shown that it is possible to provoke a carcinogenic response in rodents by a wide diversity of experimental procedures, many of which are considered to have little or no relevance for human risk assessment. The outcome of the Standard Chronic Bioassay has been shown to be positive for about 50% of a random selection of chemicals in the US NTP program (22). These bioassays have frequently identified different target organs in rats and mice and even in different strains of one species. Further, the data from bioassays were often contradictory, with simultaneous increases and decreases of tumors in different tissues (23).

Drugs have to be administered at very high doses (MTD). The paradox is that the safer the chemical, the higher the MTD, and the more likely that biochemical distortions will lead to cellular injury or cell death, abnormal compensatory cell replication, toxic hyperplasia, and toxicity-induced cancer, which is not considered relevant to man (24). A comparative study between animal experiments and epidemiological studies on chemicals also showed that animal studies with test doses above the MTD resulted in carcinogenic effects in multiple organs that had no or limited predictive value for man (25).

The IARC has provided additional indications for the lack of human relevance by the chronic bioassay. IARC work groups have evaluated hundreds of pharmaceuticals for their carcinogenic properties. However, only 20 pharmaceuticals were conclusively carcinogenic to humans and 52 were "probably" or "possibly" carcinogenic (13, 14). The pharmaceuticals known to cause cancer in humans each possess at least one of the four

properties: genotoxicity, immunosuppression, hormonal activity, or chronic irritation (cytotoxicity/mitogenic activity). These properties can be identified by genotoxicity studies *in vivo* and in well-designed toxicology studies of up to 6 months duration in rats (26). The absence of effects in humans was also considered to be due to an exposure in man below the threshold dose for the epigenetic effects or due to cancer mechanisms that were specific to the rodent test animal.

Therefore, the findings from nongenotoxic compounds can be shown to lack relevance for humans because either the animal exposure is excessive as compared to human exposure, or the response to a carcinogenic challenge is qualitatively different in rodents from that in humans (26). In case of a different mechanism, additional mechanistic studies often have to be performed to prove the lack of relevance to man.

International Conference on Harmonization (1991–1997)

Since 1991, the International Congress of Harmonization (ICH 1, 2, 3, and 4, respectively, taking place in 1991, 1993, 1995, and 1997) has met to promote harmonization of regulatory requirements between its regions (Japan, US, and Europe) on Safety, Quality, and Efficacy of human pharmaceuticals. Both regulatory authorities and industry associations were involved in these discussions.

Based upon the deficiencies of the standard chronic bioassay as well as on increased mechanistic knowledge, the following needed to be defined: 1) when carcinogenicity studies should be performed; 2) the use of new methods in carcinogenicity testing, and 3) guidance for dose selection (27). These three safety topics are described in more detail in Table 5.

As indicated in Table 5, carcinogenicity studies (see S1A) are only required for long-term human exposure of chemicals, but may also be recommended if there is cause for concern even with compounds lacking long-term exposure. ICH topic S1B takes into account the recent scientific developments, rather than harmonizing between nations. Several large databases of long-term rodent carcinogenicity studies conducted over the past 25 years indicate consistently that approximately 50% of chemicals yield a positive result. These pharmaceutical databases derived from pharmaceuticals only were based upon the shortcomings of the Standard Chronic Bioassay previously described. The pharmaceutical databases are summarized in Table 6.

The ICH addressed several main questions. These included: "Would the use of rats, but not mice, result in loss of information on carcinogenicity that would be relevant to human risk assessment?" and "Has a positive

Table 5 ICH topics on carcinogenicity testing

S1A. “Need for carcinogenicity studies”
Required for any pharmaceutical with expected “clinical use of at least 6 months”
Recommendation if there is “cause for concern:”
1. Previous demonstration of carcinogenic potential in a product class that is considered relevant to humans
2. Structure-activity relationship (SAR) suggesting carcinogenic risk
3. Evidence of preneoplastic lesions in repeated dose toxicity studies and
4. Long-term tissue retention of parent compound or metabolite(s) resulting in local tissue reactions or other pathological responses
S1B. “Testing for carcinogenicity of pharmaceuticals”
Flexibility and judgement should be exercised in the choice of approach.
Either 2 long-term carcinogenicity studies (one in the rat and one in the mouse) or one long-term study plus one other study with a shorter duration (“one plus approach”).
S1C. “Dose selection in carcinogenicity studies”
Criteria for dose selection in carcinogenicity studies:
1. Toxicity-based endpoints (MTD)
2. Pharmacokinetic endpoints (25-fold AUC ratio: rodent-human)
3. Saturation of absorption (highest exposure reached)
4. Pharmacodynamic endpoints (e.g. sedation at high dose levels)
5. Maximum feasible dose (e.g. maximal solubility reached)
6. Other additional endpoints.

result in mice (but not in rats) correctly prevented a nongenotoxic drug from being marketed”? (32).

Results of the database surveys proposed that rats were more “sensitive” than mice and that tumorigenicity detected in mice only was never the sole reason for regulatory action. Furthermore, findings in rats only were twice as frequent as in mice only; all known human carcinogens were positive in rats (32). Therefore, it was proposed that normally one long-term study in one rodent species would suffice. The species should be the most appropriate and on practical convenience, the rat would be preferred. From the European point of view, one chronic bioassay in the rat would be sufficient. However from the US perspective, an additional short-term study was requested. The short-term models are further explained later in this article.

Finally, more criteria than the sole MTD were acceptable for dose selection (see Table 5, S1C). The availability of multiple acceptable criteria for dose selection provides greater flexibility in optimizing the design of carcinogenicity studies.

CARCINOGENICITY TESTING IN THE FUTURE

Alternative Carcinogenicity Models

According to ICH S1B, a “one plus approach” might be possible instead of the 2-year bioassay in rats and mice. In this approach, the species to be used in the one long-term study should first be selected, and secondly, the

Table 6 Overview of pharmaceutical databases

Continent	Scope	Reference
IARC (France)	International Agency for Cancer Research	13, 14
FDA (US)	Food and Drug Administration	28
PDR (US)	Physicians Desk Reference	29
JPMA (Japan)	Japanese Pharmaceutical Manufacturing Association	30
CPMP (EC)	Committee for Proprietary Medicinal Products	31
CMR (UK)	Center for Medicines Research	30

alternative model should be chosen, both based upon various selection criteria. Selection criteria for both the species and strain to be used in the long-term study and in the alternative model are summarized in Table 7. A description of the various alternative short-term models is given.

Transgenic mice

Transgenic mice may provide advantages in developing a more specific model and reducing the number of animals and the time required for bioassays (6–9 months daily dosing). Such models include transgenic mice that carry reporter genes that may serve as targets for genotoxic events or mice carrying specific oncogenes or inactivated tumor suppressor genes that are important factors that contribute to the multistage process of carcinogenesis.

Table 7 ICH S1B “testing for carcinogenicity of pharmaceuticals”: Rationale

Select most appropriate species for the long-term study:

Based on comparative studies in two or more rodent species:

1. Pharmacology
2. Repeated dose toxicity studies
3. Metabolism
4. Toxicokinetics
5. Route of administration
6. In the absence of clear evidence favoring one species, the rat is recommended.

Select most appropriate alternative model:

Models:

1. Transgenic rodents (in vivo)
2. Neonatal rodents (in vivo)
3. Initiation–Promotion models (in vivo)
4. Syrian Hamster Embryonic cell (SHE) assay (in vitro)

Prior to inclusion of any new method, it is critical that the method be evaluated for:

1. Is new, additional information expected?
2. Will concerns be addressed?
3. Is there a comparable metabolism in man?
4. Is there a comparable exposure in man?
5. Is there literature or other evidence on the value and relevance of the model?

Mouse lines with defined genetic alterations that result in over-expression or inactivation of a gene intrinsic to carcinogenesis, but that are insufficient alone for neoplastic conversion, are promising models for identification and evaluation of rodent and/or human carcinogens. Likely models are:

1. Transgenic animals that over-express (proto-) oncogenes, such as:
 - a. “TG.AC” mouse line (a “skin-painting model”), which expresses a mutation of the “v-ras” proto-oncogene (33).
 - b. “Tg-rasH2” mouse line, which expresses a mutation and amplification of the human “c-Ha-ras” proto-oncogenes in different tissues (34).
2. Transgenic animals that lack certain genes (“knockout” animals), such as:
 - a. “P53 +/-” mouse line, which expresses heterozygous inactivation of the P53 “tumor suppressor gene,” which is critical to cell cycle control and DNA repair (33).
 - b. “XPA-/-” mouse line, which expresses homozygous absence of “DNA-repair genes” (35).

Neonatal mice

Neonatal rodents have been studied since the 1960s. The test on newborn rodents (12 months of duration) has been extensively investigated in the United States and in Japan, and has been demonstrated to be highly sensitive to genotoxic carcinogens (36).

Meanwhile, further investigations have revealed that dosing on days 8 and 15 of age at the MTD and at half the MTD appears to be the current dosing regime, followed by a 12-month observation period.

The susceptibility of neonatal mice to tumorigenicity has been demonstrated and is explained by the fact that metabolic activity of a chemical in neonates is in the developing stage. Delay of excretion of a chemical via metabolic pathways results in prolongation of the presence of a chemical in the body. Such prolongation of the presence of a carcinogen would have a greater chance of changing normal cells into tumor cells.

Initiation—promotion models (in vivo)

The principle of this model is that in order to evaluate a substance as an “initiator,” it will be administered in a single dose or over a period of several days or weeks. After several weeks of washout, a “promotor” (e.g., phenobarbital) is administered, and several months later, the number of pre-neoplastic or neoplastic changes are examined.

To evaluate whether an agent acts as a “promotor,” the procedure is reversed. Following initiation with a known initiator (e.g., diethylnitrosamine), the substance under investigation is administered intermittently, at different dosages, over a number of months. In retrospect, this model might be valuable in establishing the mechanism underlying carcinogenicity (17).

Syrian hamster embryo (SHE) cell transformation assay (in vitro)

In this system, normal cells are isolated from 13-day-old embryos, and these cells are treated with carcinogenic agents capable of inducing genetic alterations that can produce changes in cellular and colony morphology that result in “morphologically transformed” SHE cells. These cells will senesce unless they undergo the additional genetic alterations necessary to acquire immortality and tumorigenicity. Several intermediate stages in this system, including morphological transformation, immortality, acquisition of tumorigenicity, and malignant progression, shape the alterations observed during *in vivo* neoplastic transformation and possibly explain why the SHE assay is able to identify rodent carcinogens (37). In the SHE assay, compounds are cultured over a period of 24 h–7 days, and colony formation is examined as the endpoint of clonal transformation.

Evaluation, Validation, and Implementation of the Alternative Models

Further description of alternative models and their evaluation and validation is given by Blain et al. (38). Validation exercises are taking place at the American National Institute of Environmental Health (NIEH), the International Life Science Institute/Health and Environmental Sciences Institute (ILSI/HESI) (39), the Japanese Central Institute for Experimental Animals/National Institute of Health Sciences (CIEA/NIHS), and the Dutch Public Institute for Safety and Environment (RIVM).

The NTP is also evaluating several lines of genetically-altered mice for possible use in identifying and assessing carcinogens. A number of comments and concerns were raised, offering some thoughts on future directions for this line of research as well as for the possible ways in which genetically altered mice might be integrated into a comprehensive testing strategy (40).

In the industry, the ICH S1B guidelines have been implemented, and have led to changes in carcinogenicity

testing approaches, as well as changes in evaluation by the regulatory authorities. Guidelines increase flexibility, which in turn obligates industry and regulatory authorities to use more scientific, evidence-based decision-making. The changes are anticipated to significantly improve the relevance of the assessment of carcinogenic risk for humans, but might also lead to confusion and occasional disagreement on appropriate test strategies for specific drugs (41). Alternative test models might be used in various scenarios as follows: 1) as an alternative to a second 2-year rodent carcinogenicity study; 2) as a complementary confirmatory study for drugs with equivocal carcinogenicity findings in 2-year studies; 3) as a preliminary screen to set priorities for full carcinogenicity testing; 4) as an alternative to repeating a 2-year rodent carcinogenicity study; or 5) to assess the carcinogenic potential of genotoxic contaminants or degradation. Based upon available information, there is sufficient experience with some *in vivo* transgenic rodent carcinogenicity models to support their application as complementary second species studies in conjunction with a single 2-year rodent carcinogenicity study when appropriately justified (42). Therefore, a weight-of-evidence approach is justified.

Weight-of-Evidence Approach

A weight-of-evidence analysis on the level of suspicion for a carcinogenic risk should be performed based upon all available pre-clinical information that could raise concern for carcinogenicity. These concerns include carcinogenicity results, structure-activity-relationship (SAR), class evaluation, genotoxicity findings, repeated dose toxicity findings, interspecies comparison of pharmacodynamics, exposure and metabolism, and information on the intended clinical use, patient population, dose regimen, and pharmacokinetics and pharmacodynamics. SAR consists of finding the relationship between different (usually computable) characteristics of the molecules and the induced biological activity. The resulting model can be used for predicting (estimating) the biological activity, and in this case, carcinogenicity. Various commercial computerized systems are available for SAR, as described by Richard (43). However, the performance of SAR is still limited and affected by over sensitivity (43, 44).

Schwetz and Gaylor proposed a potential strategy for the weight-of-evidence approach that includes alternative carcinogenicity models (45). This strategy proposes alternate approaches, according to SAR, or findings in the toxicity and genotoxicity studies that would provide more mechanistic information.

Elements that should be included in the weight-of-evidence approach, including alternative models, are provided by Contrera and DeGeorge (42). These include evaluation of the results of carcinogenicity studies (including alternative models) and genotoxicity studies, as well as assessment factors in the consideration of the adequacy of the test models and risk-benefit considerations. It is apparent that different tests might be warranted for the various regulatory areas, such as pharmaceuticals, food additives, environmental, or industrial chemicals (42, 45).

Another option of performing a weight-of-evidence approach “before” starting the classical and/or alternative carcinogenicity bioassays is to submit a “Carcinogenicity Testing Strategy Paper” to the authorities (46). In this way, a dialogue between authorities and industry can be reached in order to effect an agreement on the approach and dose selection prior to initiation of pivotal studies.

In the United States, the Center for Drug Evaluation and Research (CDER) engages in dialogue with industry to reach agreements on “approach” and “dose selection” prior to initiation of pivotal studies (41). In addition, a procedure of scientific advice can be found in the European Medicines Evaluation Agency (EMA)/Committee for Pharmaceutical and Medical Products (CPMP). This agency is open for questions regarding the requirement for a rationale. Companies are encouraged to inform the CPMP of the proposed carcinogenicity testing strategy (47).

Other Future Opportunities

Data from short to medium-term toxicity studies that precede carcinogenicity studies reveal that most of the nongenotoxic agents which induce tumors in rodents also produce other pathological changes in the tissues in which the tumors develop and at dose levels at which tumors are observed. These early changes range from altered hormone levels, impaired ion balance, and organ enlargement to specific and marked histopathological changes (48). These findings may be used for early detection of nongenotoxic carcinogens, and may also be extremely valuable for designing protocols for long-term bioassays. Furthermore, a thorough understanding of such early indicators will lead to the elucidation of specific mechanisms involved in carcinogenesis. Together with examination of possible thresholds for underlying toxic events, this confirms the basis for assessment of carcinogenic risk and for the regulation of human exposure.

Based upon the above rationale, a “tier approach in carcinogenicity testing and assessment” of pharmaceuticals can be followed, possibly with refinement, reduction,

or replacement of test methodologies in carcinogenicity testing.

A first approach, according to the ICH S1A guideline scenario on the need for carcinogenicity testing, prescribes long-term carcinogenicity testing (in one or two species) for compounds with continuous or intermittent exposure to humans and compounds with cause for concern. If there is no long-term exposure to the compound, and if there is no cause for concern, no further action is recommended, whereas short- or long-term studies may be warranted for suspicious findings (46).

A second approach postulates that much of the information necessary to assess the carcinogenic potential of a new drug without a bioassay is usually available by the end of the first clinical studies in patients. (Suspicious findings from *in vivo* genotoxicity studies and 3–6 month toxicology studies aimed at assessing risk factors associated with carcinogenicity in humans include: genotoxicity, immune suppression, hormonal activity, and chronic irritation/mitogenic activity.) Evaluation of this package will, therefore, identify the presence or absence of the known causes of cancer from pharmaceuticals in humans, under conditions relevant to the use of the drug in question. If cause for concern remains at this stage, useful information on long-term adverse effects that might represent a carcinogenic hazard to humans may be obtained (e.g., from a 12-month study, usually in rats, conducted at clinically relevant dose levels) (49).

Finally, a third approach has been proposed with five stages that focus on the chemical structure, DNA-reactivity, epigenetic effects, limited bioassays, and finally, the application of “accelerated bioassays.” These accelerated bioassays require 40 weeks and apply to the use of sensitive markers for induction of neoplasia in comparison to positive control compounds for important organs in human carcinogenesis. It enables data acquisition of the entire carcinogenesis process directed toward developing mechanistic information. This system would have the potential to replace the chronic bioassay in rodents in some circumstances and could serve as an alternative to a chronic bioassay in a second species (50).

CONCLUSION

In the 20th century, the concept of carcinogenesis and carcinogenicity testing has evolved enormously, although the standard Chronic Bioassay still contains many of deficiencies. New carcinogenicity testing strategies, however, are to be expected. Also, validation results

with regards to the alternative carcinogenicity models will become available and lead into new insights in the most appropriate short-term carcinogenicity studies.

A weight-of-evidence or tier approach to the level of suspicion of carcinogenic risk will be the main objective, and will include SAR and findings from sub-chronic to chronic toxicity testing (genotoxicity, reproductive toxicity, and organ toxicity). In addition, communication between industry and regulatory authorities will be formulated early in order to allow the most optimal scientific approach.

INTRODUCTION

Overview

This article is intended to be an overview of clinical data management systems and the processes they support. Data management systems are highly dependent on the size and complexity of the organization using them. Systems can range from a set of SAS data sets to a fully integrated, distributed set of applications using a relational database. The entire data management process may employ a variety of technical solutions.

The information presented here is based on experience with processes and technology in a large international pharmaceutical company. Many of these concepts are employed in smaller pharmaceutical companies and contract research organizations (CROs) but on a lesser scale.

The core data management processes are represented in the study lifecycle illustrated in Figs. 1 and 2.

Re-Engineering

The pharmaceutical industry is under constant pressure to bring drugs to market more quickly and less expensively, without compromising the quality of the products. The desire to achieve a profitable balance between these three objectives—speed, cost, and quality—results in perpetual “re-engineering.” The investment put into developing and implementing a solid database and streamlining data management tools and processes can contribute greatly to the success of this effort.

How Technology is Driving Changes in Data Management

The introduction and proliferation of the Internet and web-based applications is having a profound impact on the

conduct of clinical trials. The Internet provides us with the ability to communicate easily with CROs and investigators; and them with us, without compromising corporate security. Data sets can easily be placed on a secure web site for being reviewed and updated by a partner. Remote data entry will reach its full potential as a result of the introduction and acceptance of internet technology.

STUDY SET-UP

Standardization

To avoid redundancy, many parts of the study and set-up processes can be standardized and reused (Fig. 1). For example, as case report forms (CRFs) are developed for use across studies, the corresponding components of the study definition (questions, response values), the validation checks, reports, and extract data structures can be reused as well, especially within a drug project. This standardization allows for more efficient use of resources and systems, as well as realization of benefits in CRF design, study definition, validation, analysis, reporting, metrics, and training. Standards for data collection and processing are also necessary to fulfill the reporting requirements for pooled analyses across a project (e.g., safety updates, integrated reports, summaries).

Protocol Development

The protocol must contain a clear statement of the objectives of the investigation (primary and secondary endpoints) and the methods of analysis to be used. The various sections may be written by the appropriate team members and assembled by the clinical representative who is the protocol author. Once the protocol is complete, the

CRF is designed. The CRF is the principal document used to collect the study data and guide the study definition in the data management system.

In-House vs. Outsourcing to CROs

Once the project team completes a protocol synopsis, in-house resources should be evaluated. Consideration is given to the type of study required along with the study's priority within the project. The advantages of doing the data management in-house include:

- All data for project resides on one database
- Full control over study set-up
- Re-use of tools already developed
- Real-time access to data
- Control over study costs.

If in-house resources are limited and the decision is made to outsource data management activities, the planning process begins by creating a detailed scope of work statement and issuing the request for proposal (RFP). Bids should be solicited from several CROs.

In choosing a CRO, consider the following:

- Depth of experience in data management
- Compatibility of computer systems
- Qualified technical support for data transfer
- SOPs and policies that meet GCP criteria
- Interpersonal compatibility
- Price

Previous sponsor experience with the CRO, the CRO's track record of delivering, and the CRO reputation within the industry are more important than price.

When a CRO has been chosen, the contract should include a detailed definition of the scope of work required along with a clear understanding of when the data is considered clean and ready for analysis. A test run of data transfer from the CRO to the sponsor should be done early in the study to identify any problems in data formatting and transmission. The milestones and deliverables must be tracked closely during study conduct in order to ensure that appropriate progress payments are made. The importance of regular communication cannot be overemphasized. The early identification and resolution of technical or process problems is necessary for a smooth database closure and transfer of data. Transfer of data often contains more issues and surprises than anticipated.

The sponsor must take the time to gain a thorough understanding of the CRO's organization, work processes, and needs with respect to the project. In turn, the CRO must understand the sponsor's structure, organiz-

ation of the project management team, and the role the CRO is expected to fill in the overall operational process of the clinical study. This building of mutual understanding takes time and effort but is crucial for project success.

The project team requires reports to track the progress of the study including patient enrollment data, discrepancy counts, outstanding CRF pages, and terminated patients (including dropouts). If the CRO already has adequate tracking systems, the reports should be evaluated and adapted as needed.

After study completion, a review of the CRO's performance and a written report of lessons learned will provide information for future planning of projects and outsourcing needs.

There are several options for the transfer of CRO-processed data back to the sponsor. Most often, the final data are entered into the CRO's database to produce the final study reports with corresponding datasets. However, with the advances in the Internet and in distributed study conduct, it is possible, and generally desirable from the sponsor's viewpoint, for the CRO to enter data directly into the sponsor's database.

CRF Development

The CRF design process can begin either following or concurrent with the protocol development. Well-designed data collection forms are critical to achieve the objectives of the clinical trial. Consideration should be given to the content, format, and layout of the forms since all these factors contribute to the overall quality and accuracy of the data that will be collected, processed, and reported.

Many disciplines should participate in the CRF design stage. The core team will generally consist of representatives from statistics, data management, forms design, medical and clinical monitoring groups, with other specialists, consulting, as necessary. The primary objective of the team in this process is to optimize and balance the following requirements for the CRF:

- To facilitate the investigational site in filling out the forms correctly
- To allow for quick and accurate data entry
- To ensure that data can be analyzed and that they represent the patient's experience for statistical and clinical reporting
- To facilitate the pooling of data across a project for safety updates and integrated safety and efficacy reporting
- Consistency within project or area (e.g., pharmacoeconomics, clinical pharmacology) to allow reuse of tools.

The forms should only collect data that are needed for reporting purposes and avoid collecting unnecessary or redundant data.

The standardization of CRFs for use across multiple studies results in significant savings in the design, processing, reporting, and training resources required for a clinical study. Forms can be further broken down into modules (e.g., physical exam, vital signs, demography) or groups of questions. The use of these modules allows for greater flexibility when constructing the forms/pages while retaining the standard use of the question groups. A library of forms can be centrally gathered and maintained that includes “global” forms (those that can be used across projects—e.g., adverse events, demography), project or therapeutic standard forms (used across a project), and study specific forms.

There are many applications and systems that can be used to design and generate the CRFs. These range from word processing and desktop publishing packages to customized systems that facilitate the maintenance and use of a library of modules/forms and enforce standards. The CRF may also be in an electronic format rather than on paper, as in the case of remote data entry systems.

Randomization

Randomization is the process by which patients are randomly assigned to a treatment group. It is used to reduce the possibility for investigators and study personnel to bias the results (consciously or unconsciously) in favor of one treatment over another in a study. Randomization also allows for maintaining the blinding of a study when the blind must be broken for an individual patient. In most trials, the randomization data will be kept blinded until data are considered clean and after exclusions are decided to avoid influencing the results of a study. At the end of the trial, it is a requirement to confirm the integrity of the blinding. There must be documentation or an audit trail of all blind breaks and of all data changes post unblinding.

The statistician plays an important role in specifying appropriate parameters to be utilized in generating the randomization. The randomization specifications include treatments, centers, block size, study design, blinding requirements, and stratification factors. It is through the usage of stratification or grouping criteria that patient differences can be minimized between treatment groups.

Randomization codes are used for packaging and labeling study medications. The systems that are used to generate labels for the treatment bottles may be independent of those that produce the randomization.

Study Definition

A study definition is used to identify the system characteristics about the data fields stored within, criteria for acceptance of those data, as well as extract formats and file structures. These characteristics may include database variable name, data type (numeric, character, date/time), question name and label, short reference name (e.g., SAS^a variable name), format (e.g., ddmmyy), field length, acceptable response values (e.g., male/female), coding formats (e.g., 1 = yes, 2 = no), and validation information (e.g., validate against specific thesaurus).

Data entry screen layout is also part of the study definition. The ease (or difficulty) of data entry must be balanced with the utility of the data extract file structure, both of which are greatly determined by this process. Therefore, good database design requires the close cooperation and compromise between data management and statistics to ensure quality and efficiency throughout the data processing, management, analysis, and reporting lifecycle.

Many database systems have a catalog of questions or other global library capabilities to facilitate the storage and retrieval of data definition objects. Using these objects as “building blocks,” standard modules can be established and used across many studies.

This standardization saves considerable resources, not only in the study set-up process but also in training data entry personnel, coding validation checks, producing monitor reports, and for analysis/reporting. The continued usage of these standards can also allow for constant streamlining and improvement based on experience, with appropriate maintenance and controls.

Related to the study definition process, most systems require a schedule of events to be defined to instruct the system when to expect certain forms for tracking purposes and to associate date/visit with the form.

Data Quality Specifications

A data quality plan is a tool to aid in the implementation of data quality. The plan should be developed as soon as the protocol is finalized. Data quality is a shared responsibility across all functions. For example, the monitor assures quality by source document verification (SDV), and the clinician reviews listings of individual patient profiles and study “outliers.”

New data and corrections to data are usually processed nightly through a batch validation program in the clinical database. The batch validation program will identify new discrepancies that have appeared since the last execution

^aSAS is a registered trademark of SAS Institute, Inc.

of the validation. The program will also resolve any previously generated discrepancies that are no longer valid because either the data or the associated validation criteria have changed. Batch validation may also be run “on demand” if immediate validation of data is required.

With the help of the study team, data management usually prepares the validation procedures document to identify specific variables that must be validated. Edit checks may be defined as part of the data structure and executed during data entry. Programmed checks are user-defined checks executed off-line during batch validation.

These programmed checks include

- Standard checks developed for all standard CRF pages
- Project specific checks used within each project
- Study specific checks used for study specific pages of the CRF.

The completed validation checks should be run against test data to ensure they are written correctly. As the data is received and validated by these procedures, it is important to review the output and add or delete edit checks as appropriate.

STUDY CONDUCT

Receipt of Data

Technology is providing a number of options for the transmission of data from the investigator, CRO, or lab, back to the sponsor site. Imaging technology allows for the capture and efficient storage of all CRFs for use in data tracking and electronic submissions. Current and near future imaging technology will allow us to store an electronic copy of signed CRFs as well as easily archive all study-related documents. Images can be read using optical character recognition and bar coding techniques. These technologies, once perfected, will greatly reduce the manpower required to index and enter the data on CRFs into the data management systems. Imaging technology is currently being employed to route documents through the appropriate study conduct workflow (Fig. 2).

There have been numerous advances in the area of remote data acquisition. Data can be collected at the site via an electronic CRF or a hand held electronic device. These data can then be transmitted back to the sponsoring company and batch loaded into the sponsor’s clinical trial database. Remote data entry technology currently allows for the easy definition and distribution of the electronic CRFs to the investigator site. Some online cleaning can be performed as the data are entered before transmission to the sponsor site, where additional quality checks are

applied and transmitted back to the investigator site. This iterative process allows for collection and generally faster cleaning of clinical data. Data can also be transmitted from the CRO, investigator, or lab via electronic data transfer. Laboratory data are most often transmitted this way due to the volume of the data. The data are then batch loaded into the sponsor’s clinical trial database. Fax transmissions are often received from the investigator. The fax transmission can be printed out and then data entered, or the fax can go directly to a fax server or be passed through a scanner and an electronic image of the form/document can be created. This image can then be stored, or data entered either by optical character recognition, manual data entry, or a combination of the two.

Many studies are still conducted by traditional paper-based methods. CRFs and documents are sent by post (often overnight) to the sponsor site where they are data entered and filed. Today’s technology allows for the conduct at multiple sites, with the ability to pool data for interim analyses and integrated safety summaries. The size and complexity of a study should determine which technology should be employed. Most large pharmaceutical companies have a portfolio of study conduct technologies to employ.

Data Entry

In a paper-based data flow, as CRFs are received by the sponsor, the pages or forms can be “logged in” or identified to the system. A document number may be used to uniquely identify a page for further tracking within the database. This document identifier can be scanned from a barcode printed on a form, created using a document number generator, or manually entered.

Once the form is recognized as received by the system, a data entry operator can start entry into the database. In the data definition process, screen layouts will have been defined to facilitate the accurate and speedy entry. Some validation or discrepancy checks can be designed to trigger at entry. For example, if a data entry operator attempts to violate the criteria defined to the system for a particular data field (e.g., entering character information into a numerically defined field), a discrepancy can be raised to alert the operator for acceptance or correction to the data. If the entry correctly reflects what is written on the CRF, the value can be accepted and a discrepancy noted for later follow up.

Many systems allow for the option to perform an independent second pass of data entry to ensure that data that is recorded on the CRF matches what is entered into the database. Second pass (double key) should be performed by a different data entry operator than the first pass. In the cases where the first pass and second pass

do not match, the data entry operator is prompted and can accept either entry. An audit trail is kept by the system, and reports may be generated to document changes performed during the second-pass process.

Data entry conventions are recommended to assist in the consistent handling of the data. These conventions should include guidelines and rules for dealing with expected (and unexpected) issues arising on the forms. Some examples include handling missing data, illegible text or data, investigator comments, acceptable abbreviations, etc.

Not all data are received by the sponsor site on CRFs or paper. For example, data may be entered remotely at the investigator site or generated as an output file from instrumentation and then electronically transferred to the sponsor site via the Web/Internet, other connections, or even diskettes. Alternatives to traditional data entry also include using optical character recognition (OCR) technology. This scanning technique used to populate the database may require the CRFs to be designed with special considerations as to the density of the forms, increased use of coded fields, and legibility of the completed forms.

Discrepancy Management

In addition to the discrepancies generated as a result of study definition (univariate discrepancies), discrepancies may also arise when a batch validation detects data inconsistencies (univariate and multivariate discrepancies). Discrepancies are also identified by a visual review of the data, e.g., monitoring lists, SDV review. Discrepancies may also be created by people responsible for data analysis (e.g., statisticians, pharmacoeconomists, clinical pharmacologists). All discrepancies and data fields requiring verification or clarification are tracked using the clinical database.

Quality control for clinical data within data management includes computerized validation of data in the database and second-pass data entry. These activities are performed to ensure that data are complete, accurate, and

compliant with the protocol. In addition to discrepancy reports, verification of randomly selected fields may be used to assess the data quality.

Discrepancy reports are prepared for investigator review and correction. The sponsor translates the computer output into user-friendly reports. There is direct communication between the investigational site coordinator and the data manager for any error messages that may need clarification.

Corrections are made by the site representative directly onto the CRF page and then faxed back to the sponsor. If fax technology is not used, a copy of the corrected CRF page is made and sent to the sponsor by mail or courier. Good clinical practice requires that all corrections must be dated and initialed by the site representative.

Once the corrected copies are received, the data manager makes the change in the clinical database. An electronic audit trail is maintained in the clinical database of all data entered and changed. This audit trail tracks the date and time stamp and the identification of the person making the entry correction or change.

Ongoing Monitoring

A number of query tools may be used to track the quality and completeness of CRF and non-CRF data. Many of the tracking reports reside within the data management system, but tracking may also be done using simple ad hoc query tools such as Brio or even SAS. An example of on-going monitoring is the tracking of study enrollment by investigators (Table 1).

Inclusion and exclusion criteria are usually listed on the CRF. The investigator reviews the criteria and either admits or excludes the subject from continuing in the study. This may be reviewed and monitored manually by the monitor reviewing the subjects' medical records to confirm eligibility during source document verification or through reports/listing of this particular patient data highlighting any irregularities.

Table 1 Patient enrollment statistics, by investigator

Investigator	Inv ID	Site	Total enrolled	Total active	Total completed	Early terms

			34	26	8	0

Database Closure

At study completion, the data manager is responsible for assuring that the data are clean and then prepares to lock the study/close the database. The purpose of locking the study is to ensure that a full audit trail of any changes exists once the study/patients have been unblinded. Database closure marks the end of the study conduct phase and the beginning of the analysis and reporting phase. The standard definition of clean data is:

- All outstanding data in-house
- All outstanding discrepancies resolved
- SDV completed
- Clinical review of data complete
- The allocation of preferred terms to CRF verbatim terms reviewed and complete
- All non-CRF data revised and processed.

The data management system through a series of reports and internal checks provides the documentation and verification that data have been completely cleaned.

When the criteria for clean data are met, a formal sign-off meeting is held for team members and ad hoc functional representatives. With the database closure form signed off, the data manager locks the database. Locking limits the ability to change values for specific privileged users. It also starts a new audit trail of any changes made after locking.

The randomization codes may now be entered allowing the statistician to review the data in an unblinded fashion. Any pharmacokinetic data are also loaded at this time. Data management then freezes the database. No changes may be made to the existing database and no new data may be added.

Study Performance Metrics

Performance metrics are used by the study team to track and manage the study. The metrics will aid in the early

identification and resolution of problems that may affect data quality and study timelines.

For example, metrics involving patient enrollment, visits, forms flow, and discrepancies may be tracked using the clinical database. An example of a tracking report for time from patient visit to receipt in-house is given in Table 2.

Laboratory Data

It is common practice to employ outside laboratories to perform testing for safety and efficacy measures in clinical trials. Along with the results, these laboratories will also provide the units and normal ranges for the tests performed. Since the laboratories are typically utilized by many patients in a study or even across studies, it is practical for the units and ranges to be received and entered once in the system and then linked internally to the patient data to which they apply. This principle of centrally storing values that can be shared across the system is also desirable for maintaining the conversion factors used in deriving lab results into standardized units.

Thesaurus

Medical dictionaries are utilized extensively in clinical trials to assign common terminology to medical events such as adverse events reporting and clinical diagnoses, as well as to link medication trade names to their generic components. Thesaurus management systems facilitate both the ongoing maintenance of base dictionaries (e.g., COSTART, WHOART, MEDDRA) and the linkages to the reported and entered data.

Pharmacokinetic Data

In blinded studies, entering of pharmacokinetic (PK) data on an ongoing basis could jeopardize the blinding of the

Table 2 Weeks from patient visit to login, by investigator

Investigator	Inv ID	Site	Num DCIs logged	Min wks to log	Max wks to log	Avg wks to log
Smith, Michael	205000_P	15103_P	640	0.0	32.0	4.8
Sole, Thomas	205250_P	22609_P	294	1.6	35.9	12.5
Kay, James	205636_P	22938_P	959	0.1	24.1	5.7
Burn, Alan	205707_P	22997_P	731	0.1	28.1	3.7
Chub, Andrew	205708_P	22998_P	1050	0.4	32.7	3.7
Door, Robert	205709_P	22999_P	679	0.1	23.6	1.9
Field, Roy	205713_P	23001_P	637	0.0	36.6	4.8
			4990			

study. Consequently, the PK data are often entered into a separate database. The data is usually loaded into the data management system only after the study is closed and ready for analysis.

ANALYSIS AND REPORTING

Extracting Data

A well-designed data management system typically will focus on the primary objective to facilitate the collection and cleaning of clinical data. Although it must also support analysis and reporting, it is not always possible to achieve an equal balance across all these requirements; therefore, data are usually analyzed outside of the clinical database.

Data extraction is the process of selecting and copying data fields to an external file. Data extraction procedures generally produce files that are simply a reflection of the database. The data can then be manipulated and/or transposed to achieve an optimal structure for analysis and reporting requirements. Additional fields can be derived, response values standardized or decoded, and variables labeled more clearly.

Data may be organized by type of data, such as adverse events, laboratory data, demography, physical exam, etc. Since many of these categories of data exist across clinical trials, standard file structures can be designed and implemented. This standardization allows for the reuse of validated software as well as facilitates the pooling of data across studies for use in project safety summaries and other data reporting across studies.

Derivations

The derivation of data points can be conducted in a number of different ways. Usually they are calculated either in the clinical trials database or as part of the creation of the analysis ready, value added data sets.

It is advisable to store derivations for values that are not likely to change, and for which the derivation algorithm is commonly accepted in the clinical trials database. Derivations that are a result of a constantly changing database, or of a complex algorithm particular to a given study, should be conducted outside the clinical trials database and as part of the creation of the analysis ready, value added data sets.

Reporting Tools

Reporting and analysis is usually a continuous process throughout the life of a study. The “final report” is the

culmination of the efforts involved in conducting a clinical trial.

For ongoing reporting during the life of a study, there are a large number of reporting tools available on the market for the querying of clinical trials data. Each database has a number of tools that are appropriate for creating easy to mildly complex reports against the clinical trials database (i.e., Oracle^{®a} has several reporting tools). There are also a number of user-friendly query tools that are designed to retrieve data from a number of different databases. Brio^{®b} can generate query results that join multiple tables and give quite a bit of flexibility over report format and features such as sorting. More complex reports, such as a “missing and overdue forms report,” are usually written in third generation language (3gl) such as C++, or taking the data outside the database and using external programming tools. For the final statistical listings and tables, SAS is the industry standard. Where reporting is concerned, the tool that best performs the job should be the one selected.

Electronic Submission of CRFs to Regulatory Agencies

Sponsors may be required to provide selected CRFs as part of the overall package submitted to the regulatory authorities. Recently, regulatory agencies have been encouraging the electronic submission of these CRFs. Given a comprehensive and well-indexed imaging system, it may be possible to subset the requested images and electronically transfer the file with relative ease. For the situations where these files must be manually compiled, a different process may be employed. As CRFs are identified for inclusion, a scanner can be used to produce .pdf files (via Adobe Acrobat Exchange^{TMc}). An index is required to facilitate the retrieval of the forms, as desired. The collection of indexed images is then transferred onto CD-ROM for the electronic submission.

SYSTEM ISSUES

Year 2000

The approach of 2000 A.D. had caused the technology industry to take an in-depth look at all of the automated solutions employed in the industry. Every place where a date was used in an application was examined. Two digit dates were particularly troublesome as we approached the new millennium. The validation effort consumed an

^bBrio is a registered trademark of Brio Technology, Inc.

^cAdobe Acrobat Exchange is a trademark of Adobe Systems, Inc.

enormous amount of resources, both in-house and at the software vendors.

Upgrades

Whether your clinical trials management system was developed in-house or purchased from a vendor, eventually you will have the opportunity to experience an upgrade. At some point you will probably need to upgrade the operating system on the PC or server, the version of the database that your application is built on, or the application software itself. Worst case is when you have to upgrade all of these at once.

Ideally your application environment consists of a fully functional and separate test environment. It is in this area that you would test any upgrades. Testing should consist of executing documented test scripts with the goal of proving that existing functionality still works and any advertised new functionality also works.

Ideally you would try to avoid upgrading multiple pieces of your environment at the same time, as in the worst case example above. Although multiple rounds of testing is resource intensive, it is much easier to determine the source of any problems and resolve them in a controlled environment. This is a point to be aware of when choosing clinical trial software: Will the vendor support multiple versions of an operating system and database? This will give you the time to test the worst case scenario in a two-phase approach.

Conversion vs. Migration vs. Upgrade

Over time software becomes obsolete, as does hardware. Upgrading to the latest version of the software or hardware is probably the easiest path. But when you find that you must move to a completely new hardware or application environment, there are several things to consider. Often software and hardware vendors can provide the service of migrating or converting your existing data from one system to another. One should carefully investigate what this process would entail. Conversion can be a painful and extremely resource intensive operation. You should realistically look at whether it is feasible to let ongoing trials complete in the legacy system or whether it is feasible to re-enter data into the new system for smaller studies. These strategies are often much more straightforward and less error prone than a conversion would be.

System Validation

Computer systems validation (CSV) is an ongoing process that involves the evaluation and documentation of all

components of a system during its life cycle to ensure compliance with approved user requirements and quality standards. A system is defined not only by its hardware and software, but also by the processes surrounding its use. CSV is applicable to a system used to collect, process, capture, or manipulate data that may be included in a submission to a regulatory authority. Validation requires establishing documented evidence that a system meets its predefined specifications and quality attributes. Validation seeks to assure that a system has been developed, tested, and implemented in a controlled manner, performs and will continue to perform accurately and reliably, and is secure from unauthorized or accidental change. In addition to documenting the development and implementation of system components, validation includes documenting hardware and software change control, security management, and training.

Audit Trails and Change Control

It is important to be able to track the reason and source for any changes to data in your clinical trials database. Many applications have built in audit trail capabilities that track the date, time, and ID of the person entering or changing data through the application. Some applications will even prompt for a data change reason. Any changes or deletion of data should be done through the application whenever possible. Sometimes however, the volume of the data to be modified or complexity of the changes requires external intervention. If you plan to modify data in the clinical trials database from outside of the application, the process should be very carefully documented. As in any software development, the program or script that will be run to enter or update data should have a design document, that outlines the modules purpose and expected performance, as well as a set of fully executed test cases. It is common to keep all requests for manual data changes and data change scripts with their respective documents in one directory as backup for a data change log.

CHROMATOGRAPHIC METHODS OF ANALYSIS— THIN LAYER CHROMATOGRAPHY

Joseph Sherma

Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

Thin layer chromatography (TLC) consists of the sample solution being applied as a spot or band on the origin of a layer spread on a support (the plate). After evaporation of the sample solvent, the plate is placed in a sealed chamber or tank that contains a solvent mixture chosen as the mobile phase. Development occurs as the mobile phase moves up the layer by capillary forces. Instrumental development methods, such as overpressured layer chromatography (OPLC) or automated multiple development (AMD), can provide separations with increased resolution. The plate is removed from the chamber, and the separated zones are detected by physical or chemical methods, identified by comparison of their R_f values (R_f = distance of migration of the sample zone/distance of the mobile phase front) and colors to standard zones on the same plate, and quantified by visual or instrumental densitometry based on measurement of zone sizes and intensities. Zone identification is confirmed by off- or on-line coupling of TLC with visible/ultraviolet (UV), Fourier transform infrared (FTIR), Raman, and mass spectrometry (MS). Pharmaceutical applications of TLC include analysis of starting raw materials, intermediates, pharmaceutical raw materials, formulated products, and drugs and their metabolites in biological media (1).

TLC is a flexible, versatile, and economical process in which the various stages (Fig. 1) are carried out independently. The advantages of this off-line arrangement as compared with an on-line process, such as column high performance liquid chromatography (HPLC), have been outlined (2) and include the following:

1. Availability of a great range of stationary phases with unique selectivities for mixture components
2. Ability to choose solvents for the mobile phase is not restricted by low UV transparency or the need for ultra-high purity
3. Repetition of densitometric evaluation can be achieved under different conditions without repeating the chromatography in order to optimize quantification since all sample fractions are stored on the plate

4. High sample throughput since many samples can be chromatographed simultaneously (3)
5. Minimal cost of solvent purchase and disposal since the required amount of mobile phase per sample is small
6. Accuracy and precision of quantification is high because samples and standards are chromatographed and measured under the same conditions on a single TLC plate
7. Sensitivity limits of analysis are typically at nanogram (ng) to picogram (pg) levels.

Comparative studies have often found that high performance TLC (HPTLC) is superior to HPLC in terms of total cost and time required for pharmaceutical analyses (4). The Bibliography contains sources of general information on the principles, theory, practice, instrumentation, and applications of TLC and HPTLC. Detailed information on the subjects mentioned above as well as on additional topics and applications that could not be covered because of lack of space will be found in these references.

EXPERIMENTAL PROCEDURES

Sample Preparation

Sample extraction and cleanup procedures for TLC are similar to those for gas chromatography (GC) and HPLC. If the analyte concentration is sufficiently high, pharmaceutical dosage forms can often be simply dissolved in a solvent that will completely solubilize the analyte and leave excipients or extraneous compounds undissolved to yield a test solution that can be directly spotted for TLC analysis. Grinding of the sample and application of heat and/or sonication may be required to assure solubility of the analyte, as well as filtration or centrifugation to remove undissolved excipients. If the analyte is present in low concentration in a complex sample, solvent extraction, cleanup (purification), and concentration procedures usually precede TLC in order to maximize the analyte and minimize interfering extraneous components in the test solution. Since layers are not reused, it is often

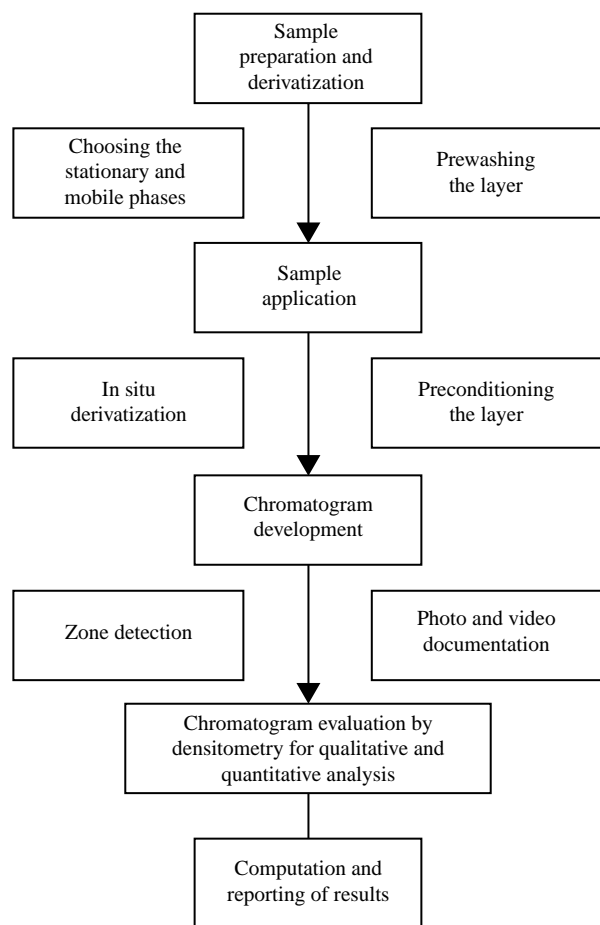

Fig. 1 Schematic diagram of the steps in a thin layer chromatographic analysis. (Adapted from Camag Scientific, Inc.)

possible to apply cruder samples than could be injected into a GC or HPLC column, including samples with irreversibly sorbed impurities.

Traditional procedures that are still widely used include liquid–liquid partitioning, column chromatography, desalting, and deproteinization (5), but the newer microwave extraction, solid phase extraction (SPE) (6), and supercritical fluid extraction (SFE) methods are being increasingly applied for isolation and cleanup of samples prior to TLC. Special plates with pre-adsorbent or concentrating zone composed of adsorption-inactive kieselguhr or silicon dioxide may provide sample cleanup by retaining some interfering substances (7).

Assay protocols for samples, such as tablets, usually involve taking multiple tablets (e.g., 10–20), grinding and mixing thoroughly, and weighing a test sample equivalent to one tablet, rather than analyzing only one tablet, so that the sample will be more representative of the batch being sampled.

Stationary Phases

Commercial precoated layers on glass support are used in virtually all analyses. HPTLC uses plates that are smaller (10×10 or 10×20 cm), have a thinner (0.1–0.2 mm) layer composed of sorbent with a finer mean particle size (5–6 μm) and are developed over shorter distances (ca. 3–7 cm), as compared to classical 20×20 cm TLC plates which are generally 20×20 cm with a 0.25-mm layer and developed for 10–12 cm. HP plates provide improved resolution, shorter analysis time, higher detection sensitivity, and improved in situ quantification and are used for industrial pharmaceutical densitometric quantitative analyses. TLC plates are usually used for qualitative identification and purity studies as contained in pharmacopeias.

Normal phase adsorption TLC on silica gel with a less polar mobile phase, such as chloroform-methanol, has been used for more than 90% of reported analyses of pharmaceuticals and drugs. Lipophilic C-18 (8), C-8, C-2; phenyl chemically-modified silica gel phases; and hydrocarbon-impregnated silica gel plates (9) developed with a more polar aqueous mobile phase, such as methanol–water or dioxane–water (10) are used for reversed phase TLC. Other precoated layers that are used include aluminum oxide (11), magnesium silicate, magnesium oxide, polyamide (12), cellulose, kieselguhr, ion exchangers (e.g., PEI cellulose anion exchanger), and polar modified silica gel layers that contain bonded amino (13), cyano, diol, and thiol groups. The polar bonded phases, in which the functional groups are bonded to silica gel by means of a hydrophobic spacer (e.g., *n*-propyl), can function with multimodal mechanisms, depending on the composition of the mobile phase. Silica gel can be impregnated with various reagents to improve separations (e.g., EDTA for tetracycline analysis) (14).

Optical isomer separations that are carried out on a chiral layer produced from C-18 modified silica gel impregnated with a Cu(II) salt and an optically active enantiomerically pure hydroxyproline derivative (15), on a silica layer impregnated with a chiral selector such as brucine (16), on molecularly imprinted polymers of α -agonists (17), or on cellulose with mobile phases having added chiral selectors such as cyclodextrins (18) have been reported mostly for amino acids and their derivatives. Mixtures of sorbents have been used to prepare layers with special selectivity properties.

Layers are often cleaned by predevelopment with the mobile phase or methylene-chloride–methanol (1:1) or immersion in methanol (19) prior to sample application, especially for quantitative TLC.

Mobile Phases

The mobile phase for a particular separation is usually selected empirically using prior personal experience and literature reports of similar separations as a guide. In addition, various computer-assisted mobile phase optimization schemes (20) have been described for selecting the mobile phase components and their relative concentrations, most notably the PRISMA model.

General mobile phases systems that are used based on their diverse selectivity properties are diethyl ether, methylene chloride, and chloroform combined individually or together with hexane as the strength-adjusting solvent for normal-phase TLC, and methanol, acetonitrile, and tetrahydrofuran mixed with water for strength adjustment in reversed phase TLC. Separations by ion pairing on C-18 layers are done with a mobile phase such as methanol–0.1 M acetate buffer (pH 3.5) containing 25 mM sodium pentanesulfonate (15.5:4.5) (21). Specific mobile phases for pharmaceutical and drug analysis are listed in the Applications of TLC in Pharmaceutical and Drug Analysis Section.

Application of Samples

The method used for application of sample solutions is determined by whether HPTLC, TLC, or preparative layer chromatography (PLC) and qualitative or quantitative analysis are being performed. Sample volumes of 0.5–5 μl for TLC and 0.1–1 μl for HPTLC are applied manually to the layer origin as spots using fixed volume glass micropipets, such as Drummond Microcaps or selectable volume 10 or 25 μl digital microdispensers. In addition, many manual and automated instruments are available for sample application, especially for quantitative HPTLC.

The partially automated Linomat IV (Fig. 2) can apply 2–99 μl volumes to HPTLC plates (5–490 μl for PLC) as bands of controlled length [1 mm (spot) to 190 mm] by spraying from a glass syringe. This instrument has been used more than any other for densitometric quantification in pharmaceutical analysis. Compact bands are also produced when 1–25 μl samples are applied manually with a digital microdispenser to plates that contain a preadsorbent zone. Band application is advantageous for obtaining the highest resolution separations and precise quantitative results by scanning densitometry.

A fully automated, personal computer-controlled spotter (e.g., the Camag Automatic TLC Sampler III), which consists of a stainless steel capillary connected to a dosage syringe operated by a stepper motor, can sequentially apply constant or variable volume samples, chosen from a

Fig. 2 Camag Linomat IV Band Applicator. (Photo courtesy of Camag Scientific, Inc.)

rack of vials, within the range of 10 nl to 50 μl as spots or bands.

Chromatogram Development

In addition to the stationary and mobile phases, separations obtained in TLC are affected by the vapor phase, which depends on the type, size, and saturation condition of the chamber during development. The interactions of these three phases as well as other factors, such as temperature and relative humidity, must be controlled to obtain reproducible TLC separations. The development process with a single (isocratic) mobile phase is complicated because of progressive equilibration between the layer and mobile phase and separation of the solvent components of the mobile phase as a result of differential interactions with the layer, which leads to the formation of an undefined but reproducible mobile phase gradient.

The important development methods in pharmaceutical and drug analysis include classical linear ascending development, horizontal development (22), gradient TLC with AMD, OPLC, and two-dimensional (2D) development. These development methods will be described briefly. Other development methods, such as circular, anticircular, continuous, and rotational, will not be covered.

In the classical method of linear, ascending development TLC and HPTLC, the mobile phase is contained in a large volume, covered glass chamber (N-chamber). The spotted plate is inclined against an inside wall of the tank with its lower edge immersed in the developing solvent below the starting line. The solvent begins to rise

immediately through the initial zones due to capillary flow. The space inside the tank is more or less equilibrated (saturated) with solvent vapors, depending on the presence or absence of a paper liner and the period of time the tank is allowed to stand before the plate is inserted. Unsaturated chambers can provide different, often higher resolution, separations as compared to saturated chambers with the same mobile phase. The twin trough chamber (Camag) (23) is an N-chamber modified with an inverted V-shaped ridge on the bottom that divides the tank into two sections. These divisions allow development with low volumes of mobile phase in one and easy pre-equilibration of the layer with vapors of the mobile phase or another conditioning liquid (e.g., a sulfuric acid-water mixture to control humidity) or volatile reagent in the other. A computer-controlled automatic developing chamber (Camag) offers programmable, reproducible linear ascending development without operator attention.

The use of a horizontal developing chamber (Camag) permits simultaneous development from both ends to the center of up to 70 samples on a 20 × 10 cm HPTLC plate, or 35 samples from one end to the other. The developing solvent, held in narrow troughs, is carried to the layer through capillary slits formed between the trough walls and glass slides. The chamber is covered with a glass plate during pre-equilibration and development, and it can be operated with controlled levels of vapor saturation and relative humidity.

Unidimensional multiple development, in which the layer is developed repeatedly for the same distance with the same solvent system or two different systems (24), is a manual method for improving the resolution of zones that migrate in the lower half of the layer (13). Multiple development has been improved by the use of AMD instruments (25), one of which is shown in Fig. 3. AMD generally involves 1–25 individual linear ascending developments of an HPTLC plate performed with a mobile phase gradient of decreasing strength (i.e., decreasing polarity for silica gel) over distances that increase by 3–5 mm for each stage. The layer is dried under vacuum and conditioned with the vapor phase of the next batch of fresh solvent before each incremental run. The repeated movement of the solvent front through the chromatographic zones causes compression into narrow bands (width about 1 mm) during AMD, leading to a spot capacity (the number of zones that can be completely separated in the available layer distance) of more than 50 for an 80-mm run. Typical “universal gradients” are produced from the solvents methanol or acetonitrile (polar), methylene chloride, diisopropyl ether, or *t*-butylmethyl ether (medium polarity), and hexane (nonpolar). Mixtures containing compounds with widely

Fig. 3 Automated multiple development instrument (AMD 2). (Photo courtesy of Camag Scientific, Inc.)

different polarities can be separated by AMD on one chromatogram, and migration distances of individual components are largely independent of the sample matrix. AMD is the most promising development method available for modern TLC and will certainly receive increased use in the future for pharmaceutical analysis.

OPLC is a method in which the mobile phase is pumped through a layer that is sandwiched between a rigid support block and a flexible plastic membrane under external pressure of 10 or 25 atm (Chrompres 10 and 25). Mobile phase flows through the layer at a constant linear flow rate velocity in the range of 1–12 ml/min, leading to higher separation efficiency than is possible with capillary flow where the mobile phase velocity is variable. To carry out linear chromatography, the layer must be specially prepared by scraping the edges and treating with a polymer sealant to eliminate leaks during development, and by cutting mobile phase inlet and solvent outlet channels at appropriate positions. A newer OPLC instrument (BS 50) provides linear isocratic or three-step gradient development, on-line or off-line modes, analytical or preparative separations, and ready-to-use presealed 20 × 20 cm or 10 × 20 cm silica gel or C-18 TLC and HPTLC layers. Of all TLC methods, OPLC most closely

simulates HPLC. Determination of deramciciane by HPTLC-OPLC (26) and forensic and clinical drug screening (27) are examples of applications. In addition to the usual elution-type development, forced flow displacement TLC was reported for pharmaceutical densitometric analysis (28).

In 2D TLC, the sample mixture is applied to one corner of the TLC plate, which is developed with the first mobile phase, dried, and developed with a second mobile phase that provides different selectivity in a perpendicular direction. Greatly increased spot capacities of 250–400 for capillary flow development and 500–2000 for forced flow have been reported for 2D TLC. The analyses of amphetamine derivatives (13) and thyreostatic drugs (29) by 2D TLC were reported.

Zone Visualization (Detection)

After removal of the mobile phase from the developed plate by heating, zones are detected on the layer by their natural color, natural fluorescence, quenching of fluorescence, or as colored, UV-absorbing, or fluorescent zones after reaction with a reagent (postchromatographic derivatization). Zones with fluorescence or quench fluorescence are viewed in cabinets that incorporate shortwave (254 nm) and longwave (366 nm) UV lamps.

Fluorescence quenching occurs on an “F-layer” that contains a fluorescent indicator or phosphor. Compounds that absorb 254 nm UV light, particularly those with aromatic rings and conjugated double bonds, appear as dark violet spots on a green or pale blue background because the absorbing compounds diminish (quench) the uniform layer fluorescence. Many drugs quench fluorescence, and this method is very widely used for detection and quantification by scanning (30).

Universal or selective chromogenic (dyeing) and fluorogenic detection reagents are applied by spraying onto the layer, dipping the layer into the reagent, exposing the layer to reagent vapors (e.g., iodine), incorporating the reagent in the mobile phase or in the layer, or by pressing an adsorbent polymeric pad soaked with the reagent against the layer (overpressure derivatization). Examples of universal reagents that react with many compound classes are vanillin-sulfuric acid (31), anisaldehyde (32), and iodine, while ninhydrin is a selective reagent for detection of amino acids (33) and Dragendorff reagent is widely used to detect alkaloids (34). Although spray application is most widely used, dipping is more reproducible, especially when carried out in a mechanized chromatogram immersion instrument (Camag). Layers must frequently be heated in an oven or on a flat heating plate after applying the detection reagent in order to accelerate the reaction upon which

detection is based. Biological-physiological methods of detection, such as bioautography, are also employed for medicinal compounds (35).

An important advantage of the off-line operation of TLC is the flexibility afforded by the use of multiple methods for zone detection and identification. For example, the layer can be viewed under long- and short-wave UV light, followed by one or more chromogenic, fluorogenic, or biological detection methods.

Many hundreds of reagents and detection methods have been described in various literature sources (36–38).

Documentation of Chromatograms

TLC separations can be documented by photography or video recording (39). Commercial documentation systems that incorporate standard and instant photographic cameras and charge coupled device (CCD) video cameras are suitable for chromatograms with colored, fluorescent, and quenched zones. The latest approach for copying TLC plates is by use of computer imaging, and a system that incorporates a computer, scanner, and black-and-white or color printer was described (40). Digital cameras (e.g., Casio QV 200) are widely used for photographing TLC plates, but their use for quality control purposes is in question because of the potential for manipulating the file with software.

Quantitative Analysis

Quantification of thin layer chromatograms can be performed indirectly after scraping off the separated zones of samples and standards, and elution of the substances from the layer material with an appropriate solvent. The volumes of the eluates are adjusted and the solutions analyzed by use of a spectrometric method, GC, or HPLC. Scraping and elution are usually performed manually. Although direct quantification has become increasingly important, indirect analysis is still widely used (e.g., for assay of some drugs according to the USP).

Direct quantification is carried out *in situ* rather than after spot elution. The simplest direct method involves visual comparison of sample zone size and/or intensity (color) variation according to concentration against reference standards developed on the same plate (11). This qualitative/semiquantitative approach is specified in various pharmacopeias for the purity analysis of active raw materials and formulated products. These pharmacopeial methods are designed for analyses at several levels: 1) simple detection of impurities as additional spots; 2) detection and identification of impurities by comparison to the R_f values distances of standards (41); or 3) detection,

identification, and estimation of amounts of impurities by comparing intensities between samples and standard dilutions of the same compounds (42).

Most modern HPTLC quantitative analyses are performed in situ by measuring the zones of samples and standards using a chromatogram spectrophotometer (usually called a densitometer or scanner) with a fixed sample light beam in the form of a rectangular slit. A schematic diagram of single beam densitometer arranged for linear reflection (most used) or transmission scanning is shown in Fig. 4. A tungsten or halogen lamp is used as the source for scanning colored zones (visible absorption) and a deuterium lamp is used for scanning UV-absorbing zones directly or as quenched zones on F-layers. Of all possible densitometric modes, most quantitative pharmaceutical assays have been carried out by UV absorption scanning of fluorescence-quenched zones. The monochromator is a prism or, more often, a grating, and the detector is a photomultiplier or photodiode. For normal fluorescence scanning, a high intensity xenon or mercury lamp would be used as the source and a cutoff filter would be placed between the plate and detector to block the exciting UV radiation and transmit the visible emitted fluorescence. Zigzag, dual wavelength reflection scanning with a point source also has been used for pharmaceutical analysis (43).

Many modern scanners have a computer-controlled motor-driven monochromator that allows automatic

recording of in situ absorption and fluorescence excitation spectra. These spectra can aid compound identification by comparison of unknown spectra with stored standard spectra obtained under identical conditions or spectra of standards measured on the same plate. The spectral maximum determined from the in situ absorption spectrum is usually the optimal wavelength for scanning standard and sample areas for quantitative analysis. The densitometer is usually connected to a computer with software designed specifically for data handling and automation of the scanning process in modern instruments. With a fully automated system, the computer can perform the following: 1) data acquisition; 2) automated peak searching and optimization of scanning for each fraction located; 3) multiple wavelength scanning; 4) baseline location and correction; 5) computation of peak areas and/or heights of samples and co-developed standards, calculation of calibration curves by linear or polynomial (44) regression, interpolation of sample concentrations, statistical analysis of reproducibility, and presentation of a complete analysis report; and 6) storage of data on disk. In general, external standardization is employed for quantification with a calibration curve generated from a series of standards that covers the full concentration range of the analysis. Although the internal standard method is sometimes used (45), it is not normally needed, unless losses during the sample preparation steps are anticipated, since samples and standards are run on the same plate under essentially identical conditions.

Image processing with a video densitometer is an alternative for colored or fluorescence-quenched zones to the use of a slit-scanning densitometer (8). A video scanner consists of a transilluminator system for totally lighting the plate, CCD camera, computer and printer, and chromatogram evaluation software. Video densitometers cannot measure UV-absorbing zones or fluorescent zones directly; cannot scan a layer with uniform, monochromatic light of selectable wavelength; and are not as accurate, precise, or sensitive as slit scanning densitometers in their present state of development (46). One of their advantages as compared to slit-scanning densitometers is for quantification of 2D chromatograms (47). TLC with video technology is being used successfully for fingerprint analysis of herbal supplements and medicines.

Special Techniques

Transfer of mobile phases to HPLC

An important application of TLC is to serve as a pilot method for HPLC, the most widely used analytical method for pharmaceutical analysis. If the stationary phases are

Fig. 4 Light path of TLC Scanner 3. (Diagram courtesy of Camag Scientific, Inc.)

similar, TLC can predict solute retention behavior and suitability of a particular mobile phase through correlation of $\log k'$ in HPLC and R_f data in TLC. Particularly useful is detection of compounds that migrate minimally in the mobile phase and can contaminate the HPLC column during subsequent runs.

Determination of lipophilicity

The determination of the lipophilicity of drugs is extremely important because the biological activity of a molecule can generally be correlated with its ability to penetrate the different hydrophobic barriers (membranes) (i.e., with its lipophilicity or hydrophobicity). One of the best ways to determine lipophilicity is by measurement of retention characteristics [R_M values, $R_M = (1 - R_f - 1)$] of the compounds of interest by reversed phase TLC on a silica gel layer impregnated with paraffin oil or a C-18 chemically bonded silica gel layer. The study of anti-inflammatory drugs is an example of an application (48). The TLC determination of lipophilicity and other molecular parameters was reviewed (49).

Preparative layer chromatography

Analytical TLC differs from PLC in that larger weights and volumes of samples are applied as a band across the entire layer width to thicker (0.5–2 mm) and sometimes larger layers, the purpose of which is the isolation and purification of 10–1000 mg of sample for further analysis. Multiple development of the plate is commonly used (50), and the separated substances are detected by a nondestructive method (e.g., under UV light and iodine vapors), and recovered by extraction from scraped layer material. PLC can be used to isolate sufficient pure drug compounds for confirmation by spectrometry in cases where analytical TLC is not adequate for identification. Examples of pharmaceutical applications of PLC include a new sesquiterpene trimer (51) and phenylpropanoid glycosides (52).

Combined TLC–spectrometry methods

Compound identification is initially made by comparing sample and standard zones based on R_f values and colors produced by selective detection reagents. Identification is confirmed by off- or on-line combination of TLC and spectrometric methods such as visible/UV, fluorescence, FT-Raman, FTIR (53, 54), solid state (NMR) (55), MS (56), and MS–MS. Coupled TLC-FTIR (57) and other combined methods (58) have been reviewed.

HPTLC coupled on-line with spectrometric methods has been proposed as a reference method in clinical

chemistry for identification prior to quantitative analysis. This is particularly important for unequivocal diagnosis as the basis for further clinical therapeutic measures (59).

Thin layer radiochromatography

Location and quantification of radioisotope-labeled substances on a thin layer requires the use of autoradiography, zonal analysis with scintillation counting (60), or direct scanning with a digital autoradiograph (26) or a bio-imaging analyzer (61). Thin layer radiochromatography is widely used for metabolism studies of pesticides and drugs in plant, animal, and human samples, and in quality control and development of radio-pharmaceuticals (62).

Method Validation

Validation procedures are performed according to the recommendations of regulatory agencies, such as the Committee for Proprietary Medicinal Products (CPMP) of the European Economic Community (EEC) and with consideration for the special features of the TLC procedure. The following validation parameters are typically monitored: 1) selectivity; 2) stability before, during, and after TLC development; 3) linearity of the calibration graph; 4) range of levels within which the analyte can be quantified; 5) limits of detection and accurate and precise quantification; 6) accuracy (indication of systematic errors), precision (indication of random errors), sensitivity (ability to measure small variations in concentration), and ruggedness (results of the method when used by different analysts in a variety of locations). Each step of the analysis must be validated through error analysis and a suitability test, and includes sample preparation, application of samples, TLC separation, detection procedures, and quantification. Definitions, general principles, and practical approaches for validation of pharmaceutical TLC analysis are described by Szepesi and Nyiredy (42). Benchmarking studies of the assay and purity testing of phospholipids by silica gel HPTLC with copper (II) sulfate-phosphoric acid detection reagent and scanning of the brown-violet zones at 365 nm showed that HPTLC provided a cost reduction of 1:2.5 as compared to HPLC (63).

Applications of TLC in Pharmaceutical and Drug Analysis

Gas chromatography, HPLC, and TLC are complimentary methods with their own advantages and disadvantages for pharmaceutical and drug analysis. Regular reviews of the

TLC literature (64) have shown that applications to pharmaceuticals and drugs are more prevalent than for any other class of compounds.

Applications of TLC include analysis of the following sample types (65):

- Starting raw materials (plant extracts, extracts of animal origin, fermentation mixtures)
- Intermediates (crude products, reaction mixtures, mother liquors and secondary products)
- Pharmaceutical raw materials [identification, purity testing, assay, separation of closely related compounds, stability testing (10)]
- Formulated products [identification, purity testing, assay, stability testing under storage and stress, content uniformity test (66), dissolution test]
- Drugs and their metabolites in biological media such as urine, plasma, or gastric fluid [pharmacological, toxicological (67), pharmacokinetic (68), metabolic, bioequivalence, forensic, and compliance and pharmacodynamic studies].

TLC analyses are performed in a wide variety of laboratories, including government, pharmaceutical manufacturer, hospital, police, and contract testing laboratories dealing with illicit drug detection in sports, horse racing, and employment screening. For identification of known compounds and impurities, purity testing, and obtaining impurity profiles in bulk raw materials and formulations, R_f values and spot sizes/intensities between samples and reference materials developed on the same plate are compared by noninstrumental or instrumental methods using TLC systems that can separate compounds from different classes or closely related compounds within a single class. Confirmation of identity often requires use of an on-line or off-line ancillary method, such as IR, NMR, or mass spectrometry, GC, or HPLC.

The following eight general, standardized TLC systems are recommended for the analysis of drugs:

For basic drugs: Silica gel layer dipped in 0.1 M KOH and dried; mobile phases: 1) methanol–ammonia (100:1.5), 2) cyclohexane–toluene–diethylamine (75:15:10), 3) chloroform–methanol (9:1), 4) acetone.

For acidic and neutral drugs: Silica gel layer; mobile phases: 1) chloroform–methanol (4:1), 2) ethyl acetate–methanol–ammonia (85:10:5), 3) ethyl acetate, 4) chloroform–methanol (9:1).

Migration data for many drugs in these systems have been tabulated (69). Retention data for 443 drugs were reported for four other standardized silica gel systems: 1) ethyl acetate–methanol–30% ammonia (85:10:15); 2) cyclohexane–toluene–diethylamine

(65:25:10); 3) ethyl acetate–chloroform (1:1); and 4) acetone. The plate was dipped in KOH solution before development with acetone (70). The following screening system (UniTox) employs three mobile phases for normal and reversed phase TLC:

For acidic and neutral drugs: 1) methanol–water (65:35), C-18 silica gel.

For basic, amphoteric, and quaternary drugs: 1) toluene–acetone–ethanol–conc. ammonia (45:45:7:3), silica gel, and 2) methanol–water–conc. HCl (50:50:1), C-18 silica gel (71).

The USP 24/NF 19, section 201 (72, p. 1856), contains a general TLC identification test that involves a nonhigh-performance silica gel layer with fluorescent indicator, chloroform–methanol–water (180:15:1) mobile phase, and detection under 254 nm UV light for verification of the identities of compendial drugs in dosage form test solutions prepared according to the individual monographs. Section 621 of the USP 24/NF 19 (72, pp. 1916–1917) presents brief information on the equipment and procedures of classical ascending and continuous development TLC.

Analytical information and data were presented on the TLC analysis of the most widely prescribed human and animal drugs as well as illicit drugs (69). In addition, applications of quantitative TLC in pharmaceutical analysis were described (73, 74). Biennial reviews of TLC typically contain more than 75 references that describe applications to drug and pharmaceutical analysis (64).

The following are brief descriptions of TLC analyses of drugs in pharmaceutical dosage forms and biological samples that were selected as typical examples.

Analysis of Biological Fluids Using Visual Zone Comparison

Clenbuterol and salbutamol residues in animal urine (75)

1. *Sample preparation.* Solid phase extraction on C-18 column, elution with 0.1% triethylamine in methanol.
2. *TLC.* Silica gel 60 layer with concentrating zone, ethyl acetate–methanol–acetic acid (8:1:1) mobile phase.
3. *Detection.* *N*-chlorination with chlorine vapors and detection of the *N*-chloro derivatives as blue spots with iodide–*o*-tolidine solution.
4. *Qualitative screening and semiquantitative analysis.* Based on R_f value and color brightness comparison between samples and standards.

Analysis of Biological Fluids Using Fluorescence Densitometry

Cortisol in plasma and urine (76)

1. *Sample preparation.* Extraction with dichloromethane.
2. *TLC.* Extracts and standards applied in 3–6 mm bands with a Linomat IV to an aluminum-backed silica gel 60 layer, chloroform-methanol (9:1) mobile phase.
3. *Detection.* Layer dipped into isonicotinic acid hydrazide reagent for 20 s and then into chloroform-liquid paraffin (9:1) to enhance and stabilize fluorescence.
4. *Quantification.* Scanning with 366 nm excitation and 460 nm emission wavelengths.
5. *Validation.* Limit of detection 1 ng, RSD 1.4–6.3%, comparison of results to a TLC-radioimmunoassay method gave correlation coefficients of 0.97 and 0.98.

Sulfamethazine in pork tissue (77)

1. *Sample preparation.* Sulfabromomethazine added to tissue as an internal standard, extraction with water, centrifugation, and cleanup and concentration by a series of solid phase extractions using C-18 bonded silica, acidic alumina, and AG MP-1 anion exchange microcolumns.
2. *TLC.* Samples and standards applied in 6 mm bands with a Linomat IV to a silica gel 60 layer, ethyl acetate-toluene (1:1) mobile phase.
3. *Detection.* Layer dipped into fluorecamine solution.
4. *Quantification.* Fluorescence scanning of analyte and internal standard zones at 366 nm or 400 nm (Fig. 5).
5. *Validation.* Limit of detection 0.25 ppb, average recovery over analysis range (0.54–2.18 ppb) was 95.6% (standard deviation 29.4%, $n = 54$).

Analysis of Pharmaceutical Preparations Using Visual Zone Comparison

Purity test for allylestrenol bulk drug substance and tablets (78)

1. *Sample preparation.* Drug substance was dissolved in chloroform; tablets were powdered and sonicated in acetone.
2. *TLC.* 2.5 and 5 μ l aliquots of sample and allylestrenol and impurity standard solutions were manually applied in 8 mm bands to HPTLC silica gel plates, which were developed by OPLC with cyclohexane-butyl acetate-chloroform (90:12:2) mobile phase.
3. *Detection.* Spray with 10% ethanolic sulfuric acid and heat at 120°C for 2 min.

4. *Assay.* Visual comparison of sample and standard zones under 366 nm UV light.

Analysis of Pharmaceutical Preparations Using Visible Densitometry

S-Carboxymethylcysteine in syrups used to treat respiratory diseases (33)

1. *Sample preparation.* Syrup diluted with 96% alcohol-ammonia (4:1).
2. *TLC.* Samples and standards applied with a Nanomat III to a silica gel 60, 1-butanol-glacial acetic acid-water (3:1:1) mobile phase, development in a twin-trough chamber.
3. *Detection.* Plate dipped into ninhydrin reagent and heated for 3–4 min at 100°C.
4. *Quantification.* Zones scanned at 487 nm.
5. *Validation.* Detection limit 15 ng/spot, RSD 0.99–1.6%, recoveries from adult and children's syrup 100.0 and 99.5%, respectively.

Analysis of Pharmaceutical Preparations Using UV Densitometry

Salbutamol sulfate and bromhexine hydrochloride in formulations (23)

1. *Sample preparation.* Sample solutions were prepared in methanol at concentrations of 200–800 ng/ μ l.
2. *TLC.* Standards and samples applied with a Linomat IV to precoated alumina-backed silica gel 60 F layer, methanol-chloroform-triethylamine (5.5:4.5:0.05) mobile phase, development in a twin-trough chamber.
3. *Quantification.* Fluorescence quenched zones of samples and standards scanned at 276 nm.
4. *Validation.* Calibration curves linear over the range 20–580 ng/ μ l; RSDs ranged from 1.1 to 1.6% and recoveries from 98.8 to 99.6% for assay of the compounds in a syrup and tablet.

Diphenhydramine hydrochloride in tablet, gelcap, and capsule antihistamine pharmaceuticals (79)

1. *Sample preparation.* Ground powder or gel dissolved in ethanol.
2. *TLC.* HPTLC silica gel 60 F layer, samples and standards applied as 6 mm bands with Linomat IV, ethyl acetate-methanol-conc. ammonia (85:10:15) mobile phase, development in twin-trough chamber.
3. *Quantification.* Fluorescence-quenched zones scanned at 260 nm.

Fig. 5 Sample densitograms: Pork tissue samples fortified with 10 ppb sulfabromomethazine (SBZ) and either 0, 1.1, or 2.2 ppb of sulfamethazine (SMZ). Origin is at 0 mm, solvent front at 53 mm. (Reprinted from Ref. 77.)

4. *Validation.* Precision ranged from 1.7 to 1.9% RSD and errors in recovery analyses of spiked samples were 0.81 and 0%.

4. *Validation.* Recoveries from laboratory-made cream were 100.1 and 100.5%, respectively, and RSD ranged from 0.68 to 1.67% ($n = 6$).

Betamethasone valerate and miconazole nitrate in cream preparations (80)

1. *Sample preparation.* Creams were ultrasonicated with 96% ethanol, and insoluble material was removed by centrifugation and filtration.
2. *TLC.* 4 μ l aliquots of samples and standards applied using a Nanomat III to a silica gel 60 F layer, development in a twin-trough chamber with chloroform–acetone–glacial acetic acid (34:4:3).
3. *Quantification.* Fluorescence-quenched zones of scanned at 233 nm.

Pyridoxine hydrochloride and doxylamine succinate in tablets (81)

1. *Sample preparation.* Tablets were powdered, sonicated in methanol, and the solution filtered.
2. *TLC.* 5 μ l aliquots of samples and standards applied as 6 mm bands to HPTLC silica gel 60 F layer with the Linomat IV, acetone–chloroform–methanol–25% ammonia (7:1.5:0.3:1.2) mobile phase.
3. *Quantification.* Fluorescence-quenched zones scanned at 269 nm.

4. **Validation.** Linearity range 0.5–2.0 µg/spot; RSD 0.73 and 1.93%, and recoveries 99.3–103% and 97.7–101%, respectively.

Analysis of Pharmaceutical Preparations Using Fluorescence Densitometry

Amlodipine besylate in tablets (82)

1. **Sample preparation.** Tablets powdered, dissolved in methanol, and filtered.
2. **TLC.** Samples and standards applied to a silica gel 60 F layer with a Linomat IV, developed with chloroform–acetic acid–toluene–methanol (8:1:1:1) mobile phase in a twin-trough chamber.
3. **Quantification.** Fluorescent zones scanned at 366 nm.
4. **Validation.** Minimum detectable limit 0.2 ng; recovery from pre-analyzed tablet spiked with three different levels of the drug standard was 100.1%.

Analysis of Pharmaceutical Preparations Using Scraping and Elution of Zones

Sulfur in topical acne medications (83)

1. **Sample preparation.** Liquid and cream samples dissolved by boiling with acetone or chloroform.
2. **TLC.** Samples and standards applied as 2 cm bands, silica gel G layer, petroleum ether mobile phase.
3. **Detection.** Iodine vapor.
4. **Quantification.** Bands scraped and extracted with chloroform, UV absorption spectrometry at 265 nm.
5. **Validation.** Recovery from three spiked samples containing 3–5% sulfur averaged $99.2 \pm 2\%$, $100 \pm 2\%$, and $101 \pm 1\%$ for five replicates each.

CHROMATOGRAPHIC METHODS OF ANALYSIS—HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

R. Raghavan
Jose C. Joseph

Abbott Laboratories, Abbott Park, Illinois, U.S.A.

INTRODUCTION

Chromatography is a technique to separate individual components in a mixture. High-performance liquid chromatographic (HPLC) methods are usually preferred over other methods of quantitative analysis. The methods are usually very specific to the analyte or analytes of interest since excellent separation of individual components are easily achieved. HPLC instruments are ubiquitous since the technique finds application in biotechnological, biomedical, clinical, and pharmaceutical analyses. Additionally, HPLC is used in many other fields including chemical, cosmetics, energy, environmental, and food industries. The availability of moderately priced, reliable, efficient, and sophisticated instrumentation has resulted in the use of HPLC as a method of choice in the pharmaceutical analysis, starting from the synthesis or isolation of a potential drug to the final stage of maintaining quality control information on a formulated dosage form.

Since the fundamental theoretical principles of HPLC were established in the 1960s, the development of HPLC instrumentation has been phenomenal. Development in column packing materials led to the development of reverse-phase chromatography in the 1970s. Development of computers and automation in the 1980s led to the ease of use of HPLC. In the 1990s the development of microcolumns, specialized columns, stable detectors, coupled with integrated data acquisition, storage, and retrieval capabilities has vastly increased the speed and efficiency of the HPLC instruments.

BASIC CONCEPTS, DEFINITIONS, AND CHROMATOGRAPHIC THEORY

Basic Concepts and Definitions

In HPLC for separation of individual components, the sample is introduced into a flowing stream of a liquid (*mobile phase*) and the analytes are allowed to pass

through a layer column of packing materials of very small diameters (large surface area), called the *stationary phase*. As the analyte molecules pass through the column, carried by the moving mobile phase, there is constant interaction of the analyte molecules (or solutes) with the stationary phases as well as with the moving mobile phase. This results in a dynamic equilibrium. The differences in the equilibrium processes of the different solute molecules result in the separation of components of the mixture. When such separation is achieved by maintaining a constant composition of all the constituents of the mobile phase, the process is known as *isocratic elution*. If the mobile phase composition is changed continuously with respect to one or more of the solvents in the mobile phase, as a function of time, it is called *gradient elution*. When the *effluent* with mobile phase zones containing the analyte molecules emerges out of the column, it is passed through a *detector*, or a series of detectors. The detector signals respond as function of the solute concentration in the mobile phase zones. These signals are fed into *data processors*, which plot signal responses as a function of time. The graphic display of signals is called a chromatogram and the individual component zones are identified as *chromatographic peaks*. These peaks are characterized by the following parameters: their *peak widths*, *peak areas* or *peak heights*, and the extent of *tailing* and the *retention time* of the peaks. The instrumental set up is called a chromatograph. A typical chromatogram is shown in Fig. 1.

In HPLC solute molecules are introduced into a moving mobile phase stream. The stream passes through an inlet and emerges through the outlet of the column. Since the particles are extremely small in size (10 μm or less) and the column is fully packed, the moving mobile phase has to be pumped through using high pressure pumps. The solute molecules are only carried by the moving mobile phase. Molecules that interact with the surface of the column will be impeded and the emerging band will elute later than a band of weakly interacting molecules.

The relative migration of the solute is dependent on the thermodynamic and kinetic properties of the solute. The

Fig. 1 Typical chromatogram.

extent and quality of separation of two closely eluting peaks are expressed by *retention (or capacity) factor* (k'), *selectivity factor* (α), and *the number of theoretical plates* (N). Capacity factor is a measure of time that the solute molecules are attached to the column particles, in comparison to that of the mobile phase. Thus greater the value of k' , the greater is the interaction with the column particles. The capacity factor is dependent on the nature of the column, the organic or aqueous strength of the mobile phase, and the temperature at which the column is maintained. Experimentally measurable parameter of *relative retention time* with respect to the retention time of an active drug is computed. Under isocratic elution conditions, a value of 2–6 for capacity factor is optimal and normally values between 1 and 10 are acceptable. Greater the value of k' , greater is the resolution between adjoining bands. However, as k' increases, there is increase in analysis time, which also results in lower detection limit, because of peak broadening. By using gradient elution these two disadvantages of isocratic elution can be overcome.

The chromatographic separation process is considered *efficient* if all the components are completely separated and the peak width is relatively narrow. Theoretically, when identical molecules enter the column head in a narrow band, the band width should be the same at the outlet. However, since solute molecules can elute at

slightly different times because not all molecules will take the same path. These differences are caused by differences in the local surface area, relative physical activity of the interacting surface, the presence of stagnant mobile phase pools in crevices and pores, and minor variations of flow rate of mobile phases through these surfaces. Not all solute molecules traverse the same path and hence they might contribute to peak broadening.

Additionally, the quality of separation is evaluated by measurement of resolution, “ R ,” between two closely eluting peaks.

$$R = 2(t_2 - t_1)/(w_1 + w_2)$$

where W_1 and W_2 are peak widths expressed in the same units as retention times, t_1 and t_2 .

The greater the value of R , greater is the separation. For an R value of 1.00, solute purity is about 97.7% if each peak is Gaussian. In practice to attain a peak purity of 99.8% or greater a resolution of 1.50 is required.

The efficiency of separation, expressed as *theoretical plate number*, N , is calculated as follows:

$$N = 16(t_r/w_B)^2 = 5.54(t_r/w_{1/2})$$

where “ t_r ” is the retention time, w_B , is the peak width at the base, and “ w ” is the band width at the peak height. A

column independent parameter, H (height equivalent to Theoretical Plate, $(HETP) = L/N$, where L is the length of the column), is more often used.

Column efficiency is inversely proportional to the particle size of the column packing. Thus the efficiency of separation will follow the following order.

$$E_{3\mu} > E_{5\mu} > E_{10\mu}$$

where E is efficiency and the subscripts denote particle size.

HPLC techniques can be used for preparative chemical separations. However, this discussion will be restricted to quantitative analytical separations. For quantitative analysis a known volume of a standard solution of known concentration is injected multiple times (most compendial methods require typically five to six injections). The average peak area of the peak of interest is computed. From a comparison of the peak area of similarly injected and separated analyte with that of the standard, the concentration of the unknown in the analyte is calculated. This procedure is known as *external calibration*. However, sometimes a known compound is added to both the standard and the analyte sample. Then the ratio of the relative peak area (or some times peak height) responses of the peak of interest, and that of the added compound are evaluated. From a comparison of the relative responses of the standard and that of the analyte injections, the concentration of the unknown is computed. This is known as *internal calibration*. Sometimes, peak height is used instead of peak area. The theoretical plates, resolution of two closely eluting peaks, percent relative standard deviation values of multiple injections, and tailing factor (extent of deviation of the chromatographic peak shape from symmetrical Gaussian peak) are used as *system suitability parameters*. USP 24 (see bibliography), and other monographs provide examples of system suitability requirements and methods of measurement to meet the corresponding requirements.

COLUMNS AND MODES OF CHROMATOGRAPHY

The stationary phase in HPLC is the solid support contained in within a specified column over which the mobile phase flows effecting the separation of the individual components. The HPLC column is normally fabricated using 100- to 300-mm long stainless steel tubes with an internal diameter of 2–5 mm. They are packed with porous, microporous, spherical, or irregularly shaped particles, or particles with specific coatings with the following characteristics.

Mean particle sizes of 3–10 μm , surface area between 150 and 400 m^2/g , specific pore volume between 0.2 and 1.5 cm^3 or mL/g , and an apparent density of 0.4–0.6 g/mL . The different modes of chromatography are distinguished based on the differences in the packing materials, coupled with the corresponding compatible mobile phase components and the differences in the nature of the interacting functional groups present in solute molecules. These functional groups selectively and specifically interact with the column support material or mobile phase leading to selectivity and specificity of separation. The stationary phase chemical characteristics are altered by using suitably modified silica particles such that the differences in the functional group properties can be selectively utilized. These are summarized in Fig. 2. A brief description of the different modes of chromatography follows.

Normal Phase Chromatography

In normal phase chromatography, a polar stationary phase and a nonpolar mobile phase is used for separation. A modulator, like methanol or acetonitrile, at a suitable concentration can be used to increase the polarity of the mobile phase. Most normal phase chromatographic columns use bare silica support, which is acidic and polar. The acidic surface silanol groups, which are hydrophilic, interact differently with different functional groups in the solute molecule. The lipophilicity of the mobile phase also affect the preferential solubility or preferential adsorption on the surfaces. The use of silica support in normal phase chromatography suffers from the following disadvantages: 1) product dependent activity of silica leading to poor separation and variations from column to column and from brand to brand; 2) irreversible adsorption of strong polar solutes on the column support; 3) the necessity to control the water content of the mobile phase; and 4) slow re-equilibration of particles to mobile phase changes. Some of these problems are over come with the use of modified silica stationary phases. The silica surfaces are modified by bonding with appropriate functional groups. Cyanoalkyl or aminoalkyl or phenyl moieties are bonded to these surfaces.

Non-polar supports like polystyrene/divinylbenzene copolymers or carbon are also used as column materials. Alumina is polar and acidic while TiO_2 , and zirconia are much more neutral. They all have good aqueous stability compared to silica. Normal phase chromatography is restricted to the separation of stereochemical isomers, diastereomers, low molecular weight aromatic compounds and functionalized long chain aliphatic compounds.

Fig. 2 Silica surface and different modes of chromatography.

Reverse Phase Chromatography

Since many compounds of pharmaceutical interest are generally polar and highly water soluble, reverse phase chromatography is extensively used. In reverse phase chromatography, separation is accomplished by the use of polar mobile phases on nonpolar stationary phase. By chemically bonding silanol groups in silica, nonpolar stationary phases are obtained. Typically C₃, C₄, C₈, C₁₈ alkyl chains are bonded to silica support surfaces. Mobile phases are usually buffered aqueous solutions containing one or more of the organic solvents like methanol, or acetonitrile, or tetrahydrofuran as modulators.

The modulators reduce the polarity and decrease retention of solutes. Depending on the organic solvent used selectivity also can be modified. Column designations like octyl (C₈), octadecyl (C₁₈), refers to the length of the carbon chain attached to the silica surface. Amino, cyano, and phenyl columns can also be used in reverse phase chromatography. To increase polarity of the stationary phases diphenyl and pentafluorophenyl columns are also used. Alkylated polystyrene/divinyl benzene polymers also can be used instead of silica based supports.

In reverse phase chromatography separation may be due to either adsorption effects or due to partitioning of the solute between the stationary phase and the mobile phase.

More often, separation is probably based on both mechanistic pathways; the relative contribution of each for a specific separation process cannot be estimated. In general, C₁₈-bonded phases yield better retention and better separation compared to C₈-bonded phases because of higher carbon content in the stationary and higher non-polar interaction with the solute.

In isocratic elution, some times compounds are not fully resolved and some compounds are highly retained. The sensitivity of the highly retained compound is reduced considerably due to peak broadening. These drawbacks are overcome when gradient elution is adopted. In gradient elution, the sample is injected when mobile phase has low organic content. The organic fraction is then increased in increments to decrease polarity. These increments are usually linear. Multiple step gradients are also adopted. The capacity factor is dependent on flow rate, slope of the gradient and column dead volume. In linear gradient elution, the bandwidth is generally constant and hence the peak becomes sharper, yielding enhanced sensitivity.

Reverse phase liquid chromatography is very versatile, fast and highly reproducible. Aqueous solutions are normally used and the modifiers used are very cheap and highly pure. Separation is predictable based on the polarity, pH profile, solubility and other physicochemical characteristics of the solute molecules. Analysis time is rather short and reequilibration is generally fast. Multiple components with minor differences in polarity can be separated by appropriate choice of gradient profiles.

Stationary phases have been modified to

1. Reduce interaction of free silanols
2. Improve the stability of phases over a wide range of pH
3. Introduce functional groups on the phases that will enable prediction of selectivity for different solutes.

Only about 50% of the free silanols in silica are bonded in octyl and octadecyl stationary phases. These residual silanols contents is further reduced by a process called *endcapping*, in which hexamethyl and isobutyl groups are additionally introduced into the matrix. Endcapped columns offer better separation and retention in addition to reduced peak tailing.

Although endcapped columns offer some advantages, the aqueous instability is still problem. To overcome these problems of silica based columns, alternative supports like alumina (Al₂O₃), zirconia (ZrO₂), and titania (TiO₂) have been developed. Alumina columns are stable in the pH range of 2–12, while zirconia columns extend the range from 0 to 14. These are basic oxides and hence silanol-like interactions are eliminated. Different bonded phases can be obtained using zirconia, however, because of poor

reactivity such bonded phases are difficult to prepare with alumina supports.

Polydivinylbenzene and polystyrene polymer based stationary phases also eliminate these effects. Porous graphitic carbon provides a highly nonpolar surface with excellent chemical stability under acidic and basic conditions. However, they suffer from lower sample loading capacity and lower efficiency than conventional columns.

In spite of these efforts, silica based modified columns are still widely used. Many column-manufacturers have introduced quality control procedures for the synthesis and characterization of silica based columns. Therefore, lot to lot variations from the same manufacturers have been considerably reduced. However, identical phases from different manufacturers can yield different separation behaviors of the same analyte under identical instrumental and mobile phase conditions. (Of 13 phenyl columns investigated for an oncology, we found only three columns providing similar separation profile for a 13-component impurity mixture.)

Ion-Pair Chromatography

In reverse phase chromatographic separations, ionic compounds, being more water soluble, are not retained in the column. To increase retention and separation a strong counter ion (an organic alkyl or aryl-substituted ion of opposite charge) is added to the mobile phase. Typically alkane sulfonic acid salts or alkyl ammonium salts are added to the mobile phase. These counter ions associate (ion-pairs) with the analyte ion, while displacing the inorganic counter ion like chloride ions. Analyte is retained since the ion-pair partitions into the stationary phase like a large non-polar neutral organic molecule. This technique, also known as *ion-interaction chromatography*, utilizes the effect of pH, ionic strength, mobile phase organic content and temperature to control retention and separation.

Ion-Exchange and Ion Chromatography

Ion-exchange stationary phases consist of solid resin particles that have positive or negative ionic bonding sites incorporated in the stationary phase. The ions of opposite charge in the mobile phase are exchanged with ions on the surface. The ions of opposite charge in the mobile phase are exchanged with ions on the surface. Cation exchange resins contain covalently bound negatively charged functional groups, while anion exchange resins have positively charged functional groups. When the charged

functional groups is a sulfonate anion, it is called strong cation exchanger. Weak cation exchange resins contain such functional groups as carboxymethyl, phosphate, sulfoalkyl groups. If strongly basic quaternary amines are on the resin, it is called a strong anion exchanger. Weak anion exchangers contain weakly basic groups like aminomethyl, diethylaminomethyl groups. If these functionalities are only on the surface of the stationary phase they are called pellicular particles. When pellicular particles are used, lower eluent concentrations are adequate. When pellicular ion-exchange resins are used, ion-exchange is the only method of separation. When ions are thus separated, particularly in the separation of inorganic ions or small organic acid anions, it is called *ion chromatography*. Most modern ion chromatographic stationary phases use polystyrene divinylbenzene copolymer resins. These stationary phases have very high pH stability and can withstand strong acids and bases.

Using ion chromatographic separation and conductivity detection the inorganic anions like halides, phosphate, nitrite, nitrate, thiocyanate, and sulfate and many cation ions including transition metal ions can be detected. When quantitation of ions are carried out in a solution matrix that is weakly conducting, conductometric detection and quantitation is possible since the total background conductivity is very small. Examples include the determination of ions in sea water or tap water or from environmental streams. However, if strongly acidic or basic eluents are used, the background conductivity is high. In order to suppress the background conductivity, special suppressor columns are used, which neutralize the acids or bases after elution and before detection. New pulsed amperometric detectors (PAD) are commercially available. With the use of PADs, parts per billion levels of metal ions can be detected. Accurate quantitation of metal ions is possible since ready to use inorganic calibration standards are commercially available.

When metal ions are used as counter ions, instead of organic quaternary ammonium ions, in the packing material, the hydroxy ($-\text{OH}-$) functional groups of the carbohydrates and other sugars interact with these metals ion. Pb^{2+} , Ca^{2+} , and Na^{+} , are typical metal ions in the packing material. Depending upon the type of counter ions used, the intensity of the interaction changes and therefore, the retention between different carbohydrates vary. Some of the carbohydrates are also retained because of the size of the molecule under these conditions.

Ion-exchange chromatography is widely used for analyses of proteins, glycoproteins, peptides and other high molecular weight compounds. These organic compounds have considerable surface charge and behave like charged anions. Hence they are amenable to ion

exchange separation. To separate nucleotides of similar molecular structures, the differences in the phosphate groups of various nucleotides and the differences in their binding characteristics are used. In addition to silica based resins, acrylic polymer based resins, dextrans, and cellulose bonded phases are used for the separation of proteins. In order to preserve the biological activity during separation, hand poured columns packed with ion-exchange materials are used. Gravity flow of eluent at low temperatures is the norm for separation. Thus, ion exchange chromatography and ion chromatography are no more used synonymously.

Hydrophobic Interaction Chromatography

In hydrophobic interaction chromatography, weakly hydrophobic sorbents are used. Gradient elution with decreasing concentration of salt is used for the separation of large biomolecules, particularly proteins, by this technique. The non-polar functional groups of large biopolymer molecules (weakly) associate with the hydrophobic ligands in the stationary phase. The stationary phase consists of a highly hydrophobic organic layer. The organic layers contain short alkyl or aryl functional groups attached at the surface. These attached groups are separated with large unattached space in between these attached functional groups. Because of this wider spacing, these “*soft*” stationary phases preserve biological activity without denaturing the proteins. High ionic strength aqueous mobile phases enhance binding between the solute and the stationary phase. Then the salt concentration is decreased to decrease the ionic strength of the mobile phase. The weak mobile phases then reduces the binding and thus separation is effected.

Typical stationary phases include the following: polyvinylpyrrolidone (PVP) coated silica sorbents, monodisperse nonporous silica columns with surface bound amides or ethers and composite agarose and polyacrylamide gels. The eluent normally consists of salts at concentrations greater than 1.0 M. Typical salts include sodium phosphate, sodium sulfate and ammonium sulfate, and organic acid salts like monosodium glutamate. Protein retention is stronger with salts that increase surface tension like phosphates, sulfates, citrates, which are solvated in water than with salts such as perchlorates and thiocyanates and the like.

Typical biological compounds that are separated by HIC include, cytochrome P-450, enzymes, DNA polymerase, epidermal growth factor, glycoprotein hormones, human immunoglobulins, human recombinant DNA and canine pancreatic juice proteins. Many HIC techniques have been used for large scale purification of proteins.

Affinity Chromatography

This chromatographic technique uses a specific binding agent. The stationary phase is prepared by immobilizing one of a pair of interacting molecules on to particles of support. The immobilized molecule is referred to as a *ligand*. These ligands selectively bind to the interacting second pair in a protein or a biomolecule. For example, an antitransferrin antibody is immobilized on the support. In this example, the antibody is the ligand; the transferrin antigen in the biomolecule will bind to the surface or release out of the surface depending on the mobile phase strength. Therefore, this technique, which utilizes the differences in the affinity of the two specific interacting groups or moieties is called *affinity chromatography*.

Typical ligands may be of biological origin like antibodies, inhibitors, substrates, coenzymes, cofactors, nucleic acids, and the like, or of nonbiological origin like triazine dyes, metal chelates, boronate salts, etc. In this technique, sample is injected on to the column using a weak mobile phase called the application buffer. Under these conditions, the only interacting component is bound to the surface and hence retained in the column. The rest are washed out of the column. Then using a stronger mobile phase, called the eluent buffer, the solute of interest is released, eluted from the column, and then quantitated or collected for later use. Elution may involve two separate steps or may be a simple step gradient. This technique is used for the separation of hormones, peptides, proteins, viruses, enzymes, glycopeptides, antibodies, metal binding amino acids, etc. Affinity chromatography is further classified as bioaffinity, bioadsorption, immunoaffinity and the like depending on the nature of the ligand on the support.

Size Exclusion Chromatography

Size exclusion chromatographic (SEC) technique is used for the separation of biomolecules based on their molecular size. Synthetic and many natural polymers like polysaccharides, celluloses, natural rubber, and some proteins have chains of differing molecular weight components. When such mixed molecular weight species are present it is said to be a *polydisperse* polymer. Otherwise, the monomer is said to be monophasic. The SEC chromatographic peak is broad indicative of the elution of the different components of the polydisperse phase. The polydisperse phase is described by up to “3” molecular weight parameters that define the distribution of species. These are 1) number average, M_n ; 2) the weight average, M_w ; and 3) z-average, M_z , molecular weights. When $M_n = M_w$, the distribution is said to “Monodisperse.” M_w/M_n is a measure of the polydispersity of the system. For large biomolecules, M_n

and M_w are different since M_w is usually higher, because it is sensitive to the presence of high molecular components in the distribution. M_n , M_w , M_z are defined as follows:

$$M_n = \sum N_i M_i / \sum W_i$$

$$M_w = \sum M_i W_i / \sum W_i$$

$$\text{and } M_z = \sum W_i M_i^2 / \sum W_i M_i$$

where N_i is the number of molecules of molecular weight M_i , and W_i refers to the weight (or concentration) of M_i . The ratio of M_w/M_n or M_z/M_w shows the width of the distribution. Size exclusion chromatography is a relative and not an absolute technique.

Gel permeation chromatography (GPC) refers to the technique in which polymers that are soluble in organic solvents are separated. In These cases, more polar organic mobile phases like tetrahydrofuran, toluene, chloroform will be used. Gel filtration chromatography (GFC) is used for separation of water soluble biopolymers. Four different calibration methods are used. If absolute known molecular weight standards are used, it is called *primary calibration method*. In *secondary calibration approach*, poly-dispersity standards of material similar to samples are used. The result is then usually specified as apparent molecular weight distribution. When M_w and M_n are obtained by use of an iteration procedure using a sophisticated software program, it is called *broad molecular weight calibration*. The iteration procedure uses calibration slopes and intercepts of broad molecular weight standards with known M_n and M_w values. *Universal calibration* is obtained from a plot of $\log (M\eta)$ vs. V_e , elution volume, where η , is the intrinsic viscosity of the polymer measured at the same temperature and in the same solvent as used for the mobile phase. This technique uses on line SEC viscometers in conjunction with universal calibration.

For organosoluble polymers cross linked polystyrene or silica based packings are used. For water soluble polymers various silica based and hydrophobic polymeric packings are used. Pore sizes of the SEC packings may range from 3 to 300 nm.

In addition to refractive index detectors, specialized detectors such as on-line SEC detectors and low angle laser light scattering detectors are used for determining the distribution of molecular weights by SEC.

INSTRUMENTATION

Solvent(s) Delivery

Solvent (mobile phase) delivery is achieved using high pressure pumps. There are several types of pumps

commercially available for delivery of mobile phase through the injector, column, detectors and then to the solvent waste container. Since the column head pressure is high, the pumps operate under high pressures (50–300 psi). Most commonly used pumps are reciprocating piston pumps with check valves. These pumps are usually computer controlled. The modern pumps provide flow rate precision which is better than 0.1% in retention time.

For gradient elution at least two solvents has to be pumped and then mixed before it passes through the column. Additionally, the solvent composition is changed in a continuous linear, continuous nonlinear, or stepwise fashion. The solvents are mixed with the use of proportioning valves, and the mixed solvents reach the pump. Since solvent mixing occurs before the pump under low pressure conditions, it is called low pressure mixing. This is the most commonly used form of mixing for gradient elution. In high pressure mixing, two or more solvents are individually pumped using different pumps and then they are mixed at high pressures. Pump head leakage is a common problem in such pumps. The pump heads has to be constantly monitored or repaired for leakage.

Dissolved oxygen from mobile phase solvents has to be removed. This is accomplished by passing helium gas through the solvent container or by passing the mobile phases through helium purging units. Currently, computers that control the pumps also control vacuum degassers, which are placed in between the pump and solvent reservoir.

Autosamplers

Autosamplers are used for unattended introduction of samples from vials that are arranged either in a rectangular or circular tray. Autosampler delivers the desired volume of 1–2.5 ml with a precision of less than or equal to 0.5% for injections greater than 10 μ l. All autosamplers use mechanized valves. Majority of HPLC autosamplers belong to one of two types. In type I autosamplers the septum cap is pierced using a syringe needle, liquid is displaced into the syringe by gas pressure or plunger action to the inlet port of a six port valve injector. The filled syringe is withdrawn, moved, and the solution deposited into flowing stream of mobile phase by the use of appropriate electromechanical devices.

Type 2 autosamplers behave in a very similar way to type I except partial loop volume can be filled and delivered. Additionally, this allows the injection of low volume with high precision compared to type I autosamplers. Both types of autosamplers suffer from carry over problems if appropriate wash cycle and wash solvents are not used between each sampling from the vials.

Detectors

A liquid chromatography detector consists of sensors and an associated electronic device to send signals to a processor. Detectors are classified as bulk property detectors or solute property detectors. Bulk property detectors measure the changes in the property of the combined eluting mobile phase and the eluting solute. For example, the refractive index is characteristic of a liquid. When a solute is dissolved, the refractive index of the solution is different from that of the solvent. These change the property of the bulk solution. Although the change is due to the presence of the solute, the refractive index of the bulk as a whole is different from that of the pure solvent. Refractive index detectors and conductivity detectors are examples of bulk property detectors. Solute property detectors detect the changes in some physical or chemical property of eluting solute component of the mobile phase.

HLPC detector

A HPLC detector should have the following characteristics.

1. Excellent linear response as a function of concentration of the solute.
2. Wide linear dynamic range; the dynamic range over which the response to concentration is linear.
3. High signal to noise ratio. The noise arises as a result of fluctuations or perturbations caused to the signal as a result of temperature, pressure, or flow rate changes in the mobile phase. Noise is also caused by the electronic circuits used in the detector system. All these combined perturbations, called noise, should be low such that very low concentrations of solute can be detected.

Refractive index detectors

The most common Refractive Index (RI) detector uses a differential refractometer, which responds to the deflection of a light beam; the deflection being caused by the differences in the refractive indices of a cell through which eluant passes and that of a reference cell in which the mobile phase is contained. The response of the detector is proportional to the mass concentration irrespective of the nature of solute being analyzed.

Conductivity detector

The conductivity detector measures the conductivity of a solution containing an electrolyte. When current is allowed to pass through two electrodes, there is resistance (or better impedance) to the flow of current through the medium. This impedance decreases if conducting electrolytes are present in the eluant. This detector is mostly used in ionchromatography. Coupled with ion

suppression technology, this has become a versatile detector for low levels of inorganic ion content in analytes of interest.

UV–vis detectors

UV–vis spectrophotometric detectors are most commonly used detectors in HPLC, since most organic compounds absorb light in the UV region (190–400 nm) and a few in the visible region (400–750 nm). Fixed wavelength, variable wavelength, and diode array detectors are commercially available. All these operate based on the ability of a solute to absorb light at defined wavelengths based on the chemical structure and functional groups present in the solute molecule. The source of UV light is a deuterium or high pressure xenon lamp while for the visible range it is a simple tungsten lamp.

A beam of light is allowed to pass through a flow cell mounted at the end of the column. As the solute molecules elute from the column and enter the flow cell, they absorb radiation. The differences in the light energy, as a result of absorption, are used as a measure of quantitation. Fixed wavelength detectors operate at a single wavelength, either at 254 or at 280 nm in the UV region. In variable wavelength detector using a monochromator light of a particular wavelength (less than ± 3 nm) can be selected, passed through the sample, and then on to a photocell for detection. Currently available detectors can be programmed to change wavelengths while analysis is in progress to get a spectrum of the eluting species. Otherwise, using appropriate software, the absorbance of the eluate can be monitored simultaneously at two to four different wavelengths. This multi-wavelength detector is less sensitive compared to fixed wavelength detectors (10^{-7} g/ml vs. 5×10^{-8} g/ml).

Photodiode array detectors

Diode array detectors acquire data over the entire range of UV–vis range 190–800 nm; in some up to 1100 nm. Two different types of photodiode array detectors are available in the market. In one, to detect over an entire spectrum, light from a continuous source is passed through the cell using a rapidly rotating or vibrating grating, which passes radiation through the cell, one wavelength at a time. The signal of the photodetector is measured as a function of time over the measuring cycle. Then, from the measuring cycle, wavelength is related to time to obtain a plot of wavelength vs. signal. In the second type polychromatic light is passed through the cell and then through a holographic grating. The light dispersed from the grating is arranged to fall on a linear photodiode array. These diode array detectors are very versatile and are used to:

1. Check peak purity using “peak overlay” (normalized) methods or by computing peak ratios at two different wavelengths
2. Identify peaks by spectral matching with accumulated and stored spectral libraries
3. Generate the spectrum of the eluting peak and determine wavelength of maximum absorption of an unknown or impurity peak
4. Quantify different peaks at different wavelengths in a single chromatographic run
5. Provide graphic 3D or contour plot presentations to regulatory agencies to show the purity of the eluting chromatographic peak
6. Identify peaks, during method optimization, when the order of elution of the compounds changes.

It should be noted that the sensitivity of these detectors is lower than fixed or variable wavelength detectors. Also, if an overlapping impurity is present either in the fronting or tailing portions of the eluting peak, it can be detected only when the concentration of the impurity is greater than 2.0% relative to that of the major peak.

Fluorescence detectors

Since the fluorescence detector is a highly sensitive, picogram levels of solute can be detected by using this detector. However, this is limited to compounds that naturally fluoresce or can be made to fluoresce by reacting with suitable derivatizing agents. Even this is restricted since appropriate functional groups that undergo such derivatization should be present in the solute molecule. In many HPLC methods where this technique is utilized, the fluorescent agent is added after separation of the components. This has the advantage that the derivatization need not be quantitative. But the reaction should be very rapid, reproducible and proportional to concentration. Because it is a unique property of the solute, it offers selectivity as well as specificity of detection.

Electrochemical detector

This is also a very specific and extremely sensitive detector. The specificity arises from the need to have an electro-oxidizable or reducible functional group present in the solute molecule. Similar to the case of fluorescence detectors, solute molecules can be derivatized to yield compounds containing oxidizable (or rarely, reducible) functional groups. A desired potential is applied between a working electrode and a reference electrode connected to the flow cell. A third electrode known as auxiliary electrode is used to control the potential. As the oxidation takes place at the working electrode surface, the current

flow changes. This is monitored, amplified and presented as response using appropriate software and hardware. When the oxidation reaction is allowed to go to completion using a high surface area of working electrode and exhausting all the reactant in the flow cell, it is called a *coulometric* detector. In this case, the total number of coulombs of charge transferred is measured. However, in the most common *amperometric* detector, the solute molecules at the surface and those are very close to the surface are oxidized by maintaining the working electrode at a constant potential. This oxidation process is diffusion controlled and is proportional to concentration. Here the increase in the current flow, “*i*” is measured, amplified and the signal is presented as a function of time. Glassy carbon electrode is the commonly used electrode for oxidation. Surface coating and the resulting contamination of the surfaces leads to a decrease in sensitivity on constant use. Therefore, this detector has to be disassembled, and cleaned very often. Also this requires long equilibration time compared to other detectors. Therefore, it is not an extensively used detector compared to other detectors described in this article. The problem of electrode pollution is overcome in pulsed amperometric detector (PAD). In this technique using a gold or platinum electrode a repeating cycle of potential pulses are applied. Typically, in a one second pulse cycle, three potential pulses are applied. In the initial negative pulse the solute is adsorbed; in the second positive potential pulse the adsorbed compounds are oxidized and the increased current as a result of oxidation is measured. In the third pulse at a high much higher positive, the electrode surface is cleaned by oxidation of the electrode itself. Thus the new surface generated is used for the repeat cycling process. This is very useful in the detection of very low levels of sugars and other polyhydroxy compounds that are otherwise not easily oxidized.

Evaporative light scattering detector

In this detector, the entire eluate from the column is atomized and evaporated to form small droplets. The solutes finally remaining form particulates suspended in the atomizing gas. When these particles are allowed to pass through a light beam, light is scattered in all directions by the particles. This is known as Rayleigh scattering. However, the light scattered at 45° angle to the incident beam is viewed using appropriate optical filters and the resultant signal is electronically processed. The detector response is sensitive to the mass of the solute particles and hence it is a universal detector. The sensitivity of this detector compares with that of the RI detector.

Computers

The computers are ubiquitous and have become indispensable component of any laboratory. It serves both data processing and process control functions. As a data processor, the computer receives, stores, archives and reprocess the input signals from various detectors. Additionally, as a system processor, the computer monitors the system detectors. The data acquired for each chromatographic run can be processed appropriately to arrive at peak area or peak height or response ratios to an added internal standard. From these it can be used to calculate the concentrations of individual components in an analyte.

Through the use of appropriate software and hardware, the computer can be programmed to do the following: 1) to command injection of the samples; 2) to control and monitor, various parameters of the pump like the flow rate, composition of the mobile phase, column pressure; 3) to monitor and control column oven, and detector temperatures; and 4) to start and stop injectors, detectors and other system units. The computer also can be used to monitor system suitability parameters and reinject samples after adjusting conditions to meet system suitability. A decision tree can be constructed to allow retesting when pre-established system suitability conditions are not met. The computer can be programmed such that if conditions are not met, the system is shut down or paused until it can be attended to. Sample preparation, derivatization and other processes also can be controlled using individual computers. With multiple computers attached to a large computer called the *server*, data from a number of detectors can be monitored, stored, and archived. The computer is also used as an excellent book-keeper storing all the information regarding samples, their results, and also the conditions under which those results are obtained. The computer has become versatile tool in the highly regulated pharmaceutical industry especially to provide traceability and data integrity to required government and compendial agencies such as FDA, USP, BP, etc.

METHOD DEVELOPMENT AND METHOD VALIDATION

The method development process involves selecting appropriate method conditions for the sample in hand. It is based on prior knowledge of the sample properties, pK_a or pK_b values of functional groups, the polarity and size of solute molecules, UV-vis spectral properties, redox behavior, concentration range, solubility behavior and the like. From a knowledge of these, suitable mode of chromatography, corresponding column(s), mobile phase

composition, flow rate, choice of detectors, gradient or isocratic conditions, and the like can be selected. Once the method has been developed with some initial trials, optimization is carried out. Optimization is necessary to accomplish best possible separation of all components within the shortest possible time or in the case of low level detection, conditions have to be optimized such that required level of detection and/or quantitation can be achieved. In general, the system suitability parameters are usually evaluated and specified before method validation is performed.

Method validation is a process by which documented evidence is prepared and provided to show that the method meets the intended need. Highly regulated pharmaceutical analytical laboratories perform method validation and generate data on the following parameters, to comply with the compliance requirements of government agencies such as FDA, EPA and/or to provide data for compendial agencies like USP, BP, etc.

The parameters that define validation are accuracy, precision, specificity, linearity, ruggedness, and robustness. Accuracy is a measure of the closeness of the measured value to the true value or an accepted reference value. This is usually measured by spiking known amounts of the analyte to a matrix called the placebo, and computing the recovery of the analyte after sample analysis. Placebo contains all the ingredients of a formulation other than the active ingredient or the ingredient being analyzed. FDA and ICH (International Committee on Harmonization of Technical Requirements for Registration of Pharmaceutical for Human use) guidelines recommend collecting data from nine determinations at (at least) three concentration levels encompassing the range of target analyte concentration.

Precision refers to the degree of repeatability under the stated conditions of the method. It is expressed as percent relative standard deviation (% RSD) for a statistically significant number of analyses of samples. Precision provides a measure of day to day, analyst to analyst and instrument to instrument variation on a routine basis. The precision data provided in support are standard deviation, % RSD, confidence intervals and may also include inter laboratory variations.

Specificity refers to the ability to determine the concentration of the analyte with a high degree of confidence that the other components in the matrix do not interfere with the target analyte. The potential interfering substances include other active and inactive ingredients, impurities, degradation products of the components and active ingredient, and extractables from the container-closure system and the like. Specificity is the currently accepted terminology by regulatory agencies. In the

literature selectivity is also used to suggest specificity. [Refer (1225) of USP XXII (1900) vs. XXIII (1995) and 24 (2000).]

Linearity refers to the linear response of the detector to the analyte concentration within a specified *range*. Range, expressed in the same units as the analytical test results, is the interval between the lower and upper levels of the analyte concentration. To show linearity, a plot of response vs. concentration is provided for at least at five different concentration levels within the range. In addition, the slope and intercept of the regression line with the correlation coefficient are also provided. Normally a single standard is recommended if the intercept is very close to zero. Otherwise, quantitation, based on linear plot of multiple standards, is generally recommended.

Ruggedness is again a measure of precision. ICH guidelines include ruggedness in precision, while USP separates it. Ruggedness according to USP is a measure of the variation in interlaboratory comparison data. It is performed to establish lack of influence of test results based on operational and environmental parameters.

Robustness is a measure of how method parameters like organic content, pH, ionic strength of the mobile phase and column temperature do not affect test results when minor variations are deliberately induced in these parameters. The quality of separation of components, the accuracy and precision of the method and the like should not change as a result of these variations. (It is the belief of the authors that robustness should be part of the method development process regarding the appropriate choice of the column and the mobile phase conditions.)

Two other terms, limit of quantitation (LOQ) and limit of detection (LOD) are used especially in the determination of the analytes at trace levels. The trace level analyte may be impurities or degradation products of ingredients in a sample or it may be a solution of active ingredient at trace levels in rinse or swab samples obtained as part of cleaning validation. LOD refers to the lowest concentration of an analyte that can be detected (but not quantitated), under a given set of chromatographic conditions. Usually, it is expressed as a concentration parameter calculated using a signal to noise ratio of 3:1. LOQ refers to the concentration of the analyte that can be quantified in a sample with a predefined value of variation in precision. Normally accepted signal to noise ratio value for LOQ is 10:1. Generally, LOD and LOQ values are dictated by specific requirements, in order to ascertain reproducibility of LOD and LOQ values. Examples of specific requirements include determination of impurities at 0.05% using a 0.1% surrogate standard, or ppm quantitation or detection requirements based on equipment cleanliness and the like. For practical purposes, it is

recommended that a control solution at a known concentration of the analyte be prepared such that a peak corresponding to this analyte concentration is always detected (LOD) or quantitated (LOQ). From one of these two parameters, if experimentally obtained, the other can be calculated.

PRACTICAL CONSIDERATIONS

Sample Preparation

For many analyses, sample preparation may simply involve dissolving a known weight or volume of sample and diluting to appropriate concentration for analysis. However, extensive sample preparation may be required, if precolumn derivatization is needed. Precolumn derivatization is carried out to increase sensitivity, to induce specificity, or to separate optical isomers and to reduce or eliminate otherwise complex and expensive clean up procedures. Solid phase extraction using appropriate solid cartridges are normally used in the clean up of biological samples. Solid phase cartridges can also be used to increase the concentration of trace analyte. These purification steps can be done in situ during analysis by appropriate plumbing using six- or ten-port valves and using computer control of the pumps and valves. No matter how it is done, attention must be paid for proper sampling and preparation of samples.

Mobile Phase Preparation

Mobile phase should be prepared using HPLC grade solvents and analytical reagent chemicals only. Mobile phases should be filtered using ($\leq 0.5 \mu\text{m}$) filters to remove any particulate matter from the solvent. To eliminate dissolved air, helium sparging or vacuum degassing is necessary. In gradient elution, in order not to alter solid phase wetting and gelling characteristics, it is advisable to use at least 5% water content instead of pure organic solvents as one of the mobile phases.

System Maintenance

Pumps and columns should be cleaned of with 50:50 methanol–water or acetonitrile–water mixture to eliminate buffers from the system. Pumps, injectors, and detectors should require periodic and scheduled maintenance to keep instruments in good operating conditions. Detector should be calibrated on a regular basis using appropriate calibration standards available from NIST or other sources traceable to NIST. FDA and other regulatory

agencies require extensive documentation regarding the “health” of these instruments. Therefore, necessary and appropriate documentation should be maintained regarding details of maintenance. If there is any instrument failure additional documentation is necessary to prove that analytical results were not impacted or compromised because of these failures, if any.

Clinical Supplies Manufacture: GMP Considerations

David L. Chesney

KMI, Waltham, Massachusetts, U.S.A.

Mark L. Balboni

KMI, Laguna Niguel, California, U.S.A.

INTRODUCTION

Applicability of GMP to Clinical Supplies

The Federal Food, Drug, and Cosmetic Act (the Act), Title 21, U.S. Code, section 301 et. seq., establishes that a drug shall be deemed to be adulterated if "...the methods used in, or the facilities or controls used for, its manufacture, processing, packing, or holding do not conform to or are not operated or administered in conformity with current good manufacturing practice to assure that such drug meets the requirements of this article as to safety and has the identity and strength, and meets the quality and purity characteristics, which it purports or is represented to possess." [21 U.S.C. section 351(a)(2)(B)]. This requirement is generally referred to as "CGMP" (current good manufacturing practice), or simply "GMP."

The requirement as written in the law is obviously very broad. It does not define the specific steps manufacturers must take to comply, or the controls that must be in place to ensure compliance. A later section of the Act gives the Secretary of Health and Human Services authority to promulgate regulations for the efficient enforcement of the Act. [In practice, this authority is delegated to the Commissioner of the Food and Drug Administration (FDA).] The FDA, acting in accordance with this authority, has promulgated regulations found in Title 21 of the Code of Federal Regulations (CFR) that sets forth the definitions to be used in specifying GMP requirements for all drugs (21 CFR Part 210) and the procedures and controls necessary for manufacturing of finished pharmaceuticals (human and veterinary), found in 21 CFR Part 211. Part 211 of the regulations is what is generally meant by the term "CGMP" or "GMP" (the acronym GMP will be used in this text). While FDA gives consideration to prevailing practice in regulated industry before specific requirements are written into the regulations as being "current, good practices," FDA's final basis used to establish GMP requirements is whether the practice is "feasible and valuable" in assuring drug safety, quality,

and purity.^[1] We also point out that the final GMP regulations are the product of notice and comment rulemaking through publication, first as a proposal in the *Federal Register*. The affected public, including the industry, has an opportunity to comment on the proposed rule before it is finalized.

Because the regulations apply to all "finished pharmaceuticals," and because of the statutory requirement to comply with GMP, there is no question that the regulations apply in a binding manner to the manufacture of clinical supplies. Nevertheless, a debate has existed for many years, and even continues today, regarding exactly how and in what respects a company may differ in its approach to the application of GMP regulations to clinical supplies vs. full-scale commercial production.

BACKGROUND INFORMATION

Clinical supplies, also known as clinical trial materials, are those investigational new drug products intended for administration in human or veterinary (animal) patients during clinical trials.^[2] In many respects, there is no difference between the equipment and technology employed to manufacture clinical supplies and that used for commercial production. In other respects, for example, production scale, robustness of the manufacturing process, labeling for clinical trial materials, expiration period (and hence the need for supporting stability data), final container, and even formulation and dosage form, there are important differences that should be taken into account when designing appropriate GMP controls for clinical supplies.

Placebos used in medical treatment to bring about a therapeutic effect without a pharmacologically active ingredient, or placebos used as study controls in clinical trials for new drugs are also subject to the requirements in the current good manufacturing practice regulations (GMP).^[3] Because they lack any active ingredient, placebos clearly cannot be tested for potency, but their inactive

composition can be confirmed. This and other considerations unique to placebos also call for some degree of interpretation of GMP.

Clinical supply manufacturing operations are those areas involved in the manufacture of Phase I–IV clinical trial materials, and may include laboratory (or table-top) scale activities, operations performed in a pilot plant (with batch sizes generally larger than lab scale, but smaller than commercial scale), clinical supplies produced in facilities manufacturing commercially approved products, as well as clinical supplies produced at contract manufacturing sites.^[4]

The GMP regulations apply to investigational new drug products produced for clinical trials in humans or animals, whereas those activities earlier in the product development life cycle such as “basic research,” discovery or preclinical experimentation are not subject to GMP requirements.

FDA INSPECTIONS OF CLINICAL SUPPLY MANUFACTURERS

Under the Federal Food, Drug, and Cosmetic Act, the FDA has the authority to “...enter, at reasonable times, any...establishment in which food, drugs, devices or cosmetics are manufactured, processed, packed, or held...” [section 704(a), FD&C Act]. This authority clearly includes sites that manufacture or conduct analysis of clinical supplies (for lot release, stability, or in connection with failure investigations). The term “reasonable time” has been interpreted by the courts to mean any time-regulated operations are taking place, regardless of date, day of the week, or time of day or night. Inspections are typically not preannounced, but may be in certain cases.

In practice, FDA only occasionally inspects clinical supply manufacturing sites. However, that should not result in a false sense that an FDA inspection will never take place. Manufacturing sites should always be prepared to undergo FDA inspections. Factors that may cause FDA to inspect clinical supply manufacturers include: Review in connection with a preapproval inspection of the commercial manufacturing site; routine inspections of contract manufacturers who manufacture only clinical supplies; inspections resulting from observed product defects, especially when such defects are linked to adverse reactions in patients (such as contaminated parenterals); in reaction to recalls of clinical supplies; or other factors. The FDA inspections of manufacturing operations for clinical supplies used in Phase III trials are more likely than for operations producing Phase I or Phase II clinical trial material.

Each site should have ready access to a person or persons highly knowledgeable in FDA inspection procedure who can prepare personnel for the inspection and manage it from the company’s perspective when it occurs. It is not the purpose of this article to explain in detail how to manage an FDA inspection, but the authors highly recommend that key personnel at each site receive relevant training in preparation for an FDA inspection, and prepare detailed policies and procedures concerning the handling of FDA inspections.

UNDERSTANDING AND USING FDA DOCUMENTS

To properly interpret and apply GMP requirements to a specific context require some research and a good deal of judgment. This process can be greatly aided by reference to a variety of FDA documents in the public domain. Most are available via links found on the FDA website, www.fda.gov. Examples of useful documents include: *Guidelines*; the so-called *Points to Consider* documents issued by the Center for Biologics Evaluation and Research (CBER); *Compliance Policy Guides*; *Inspection Technical Guides*; *Compliance Program Guidance Manuals*; and others.

A key document for interpretation of GMP in a clinical supply setting is FDA’s 1991 *Guideline on the Preparation of Investigational New Drug Products (Human and Animal)*. This Guideline illustrates *when* drug development activities are subject to GMP requirements, the degree of compliance expected at certain stages of drug development, and FDA guidance for several important sections of the GMP regulations.

FDA’s position on the applicability of GMP to clinical supplies was clearly articulated in the Preamble to the September 29, 1978 revision of the Drug GMPs (*Federal Register*, Vol. 43, No. 190, 45013–45336) that stated: “GMP regulations apply to the preparation of any drug product for administration to humans or animals, including those still in investigational stages. It is appropriate that the process by which a drug product is manufactured in the development phase be well documented and controlled in order to assure the reproducibility of the product for further testing and for ultimate commercial production.”

Compliance Policy Guides are FDA internal documents that provide precedent for GMP (and other) enforcement decisions by FDA’s field offices. They are found on the “Field Operations” or “ORA” (Office of Regulatory Affairs) pages on FDA’s website under the heading “Compliance References.”

Points to Consider documents are topical policy statements by CBER on subjects such as viral inactivation, transgenic animals, and other specialized technology subjects.

Compliance Programs provide FDA investigators with procedural guidance for performing inspections in a wide variety of industries. Some (but not all) of these are also accessible via the ORA link of the FDA's website.

Industry publications and seminars can also provide useful information, but users should be wary of placing too much weight on "podium policy" statements by FDA officials or reading inspection citations issued to other companies. These sources may be misleading when the reader may not know all the facts surrounding any statements.

SELECTED GMP SYSTEMS AS APPLIED TO CLINICAL SUPPLIES

The Quality Organization

21 CFR 211.22 is the regulation that sets forth the responsibilities of the "Quality Control Unit" (QCU). There is no difference in the required roles and responsibilities of the QCU in the manufacture of clinical supplies vs. commercial products. The FDA considers the presence of an adequately staffed and trained QCU, empowered with authority to carry out its responsibility effectively, as a critical factor in GMP compliance.

Companies should be aware that "Quality Control Unit" is a generic term, and the company-specific terminology may differ from the term QCU. For example, in most companies, this unit is referred to as Quality Assurance (QA). Other common terms include Regulatory Compliance, QA/QC, or in some cases, the Regulatory Affairs group fulfills many, if not all, of the listed QCU functions. In very small companies or "virtual" firms, the QCU may be as small as one person, while in large companies the number of QCU employees may be quite large, and the quality organization may have several subdivisions. Thus, the name given to the QCU and its members is not as important as the authority to implement the required roles and responsibilities.

The regulation requires that the QCU be responsible for the following, at a minimum:

- Dispositioning (approval or rejection) of components, containers, closures, in-process materials, packaging, labeling, and finished products.
- Review of production records to assure that no errors have occurred.
- If errors have occurred, they have been fully investigated.
- Approval or rejection of standard operating procedures (SOPs) and specifications.
- Approval or rejection of changes.
- Oversight of contracted manufacturing operations (including testing).
- Approval or rejection of all activities having a potential impact on the safety, purity, potency, quality, and efficacy of the products being manufactured.

The FDA expects (and many other regulatory authorities require) that the QCU will have full independence from other units. This is to provide the maximum degree of assurance that the QCU's decisions will be free of conflicts of interest and other impediments. Normally, the expectation is that the head of the QCU will report to a very senior level person (CEO, President, COO, etc.) of the company, and that there will not be a situation where the head of the QCU reports to manufacturing, marketing, or other similar functions.

The GMP requires that the QCU should have a qualified laboratory. This may be an in-house laboratory that is part of the QCU itself, or it may be an outside contractor or another company site laboratory. Here again, there is an expectation of independence of the laboratory from manufacturing or other units, in order to assure the maximum degree of objectivity in the data that are generated.

Master (and Batch) Production and Control Records

The specific requirements for master production and control records, and batch production and control records outlined in sections 21 CFR 211.186 and 21 CFR 211.188, respectively, also apply to clinical supplies. Despite these requirements, the level and amount of available documentation for early developmental batches will generally be much less when compared to commercial products, until the manufacturing process becomes more fully defined. Batch production and control records for clinical batches produced will have an increased amount of notes, changes, and other information handwritten on them during execution of clinical batches. The amount of this extraneous information usually coincides with the stage of development for the drug product (e.g., early phase production = more notes and changes), and may include the following:

- Notes of any situations arising during production.
- Problems that occurred.

- Modifications made to the formulation, processing step sequence, processing parameters, or equipment set points.

This information that is annotated on executed master production and control records should be evaluated, reviewed and, if necessary, approved, and incorporated utilizing an established change control system.

In many cases, master production and control records used in the production of clinical supplies start out as “batch cards,” which are sometimes printed on a heavier stock paper that may be colored (e.g., blue or green), in order to differentiate them as related to R&D production operations, and not commercially manufactured products.

Buildings and Facilities

While buildings and facilities are required to be of suitable size and construction, as well as maintained in a good condition for both approved products and clinical supplies, the level of protection these areas are required to provide is dependent upon the activities taking place inside a respective area. For example, sterile fill operations necessitate, among other things, high-efficiency particulate air (HEPA)-filtered air, temperature and humidity controls, and Class 100 (Class A) environmental conditions.^[5] It would be inappropriate to perform aseptic filling operations for even Phase I clinical supplies in a nonenvironmentally controlled laboratory suite under a hood certified to meet Class 100 conditions. As it will be noted later in this article, there is little to no difference in matters of sterility assurance when comparing clinical trial materials to approved products.^[6] Similar discretion should also be exercised for operations such as dispensing, mixing, and packaging because FDA expect buildings and facilities used to manufacture clinical supplies are the same as those for commercial products.

Equipment

As with buildings and facilities, equipment must also be of suitable size and construction, as well as suitably located to facilitate its operation, maintenance, and cleaning (21 CFR 211.63). While there is clearly no difference in regulatory requirements for equipment used to manufacture clinical supplies, when compared to commercial manufacturing (e.g., equipment must be maintained and cleaned at appropriate intervals, measurement devices calibrated, qualified, and operating according to written and approved procedures), cleaning is especially important, in as much as many compounds encountered during drug development are of unknown toxicities that pose additional risks.^[7]

Generally, fully established and validated cleaning procedures will not be in place during Phase I and II clinical supply manufacture. However, the actual cleaning regimen should be robust enough to minimize the potential for contamination or product carry-over. This may be accomplished via visual inspection, or possibly by verification through actual sampling and analytical testing. Finally, 21 CFR Part 211.105 requirements regarding identification of equipment used in the manufacture of clinical trial material can be satisfied with a single sign, or placard, denoting the material in question, the phase of production, and batch number.^[8]

Control of Incoming Materials

General requirements related to incoming materials, which include components, drug product containers, and closures, include establishing and following written procedures for the receipt, identification, storage, handling, sampling, testing, and approval (or rejection) of said items (21 CFR 211.80). Research and development organizations will typically have receiving functions and areas that are separate from those used to receive incoming materials for commercial manufacturing operations. The quantities of components, drug product containers and closures, and the containers holding them are generally smaller when compared to the volumes and sizes of incoming materials received by commercial operations.

It is important to note that FDA expects incoming materials used in the manufacture of clinical supplies to be released by the Quality Unit (21 CFR 211.22). Attempts to circumvent the established receiving operation in order to expedite use of these materials should be avoided. Equally important is the requirement to ensure proper storage and segregation of incoming materials, such that quarantined, released, and rejected items are easily identified, and there is some level of separation among them. Different lots or item numbers of similar materials should not be comingled during storage, in order to avoid inadvertent mix-ups with their use in manufacturing (21 CFR 211.80).

Finally, incoming components (e.g., raw materials) used to manufacture clinical supplies must be tested for identity using a specific identity test (if available). Specifications should be established and confirmed for each lot of components, drug product containers, and closures received (21 CFR 211.84 and 21 CFR 211.94), and all other provisions of 21 CFR Part 211, Subpart E, Control of Components and Drug Product Containers and Closures not noted in this section also apply to clinical supply manufacturing operations.

Qualification and Validation Activities

Qualification activities are normally associated with buildings, facilities, utility systems (e.g., water, air handling, Clean-in-place/Steam-in-place (CIP/SIP), and compressed gases) major equipment (including laboratory instrumentation), whereas validation likely is in reference to those confirmatory tasks related to processes and analytical methods. In simplistic terms, validation (and qualification) can be defined as documented evidence that a process, activity, or piece of equipment can consistently meet its predetermined acceptance criteria and quality attributes.^[9] This section will be dedicated towards outlining the requirements for validation of manufacturing processes, as the requirements for buildings, facilities and equipment, and the validation of cleaning processes have been discussed in previous sections.

The FDA has indicated that during development, processes are expected be validated, and this should be completed to the “extent possible.” Challenges with earlier stages of development include fewer batches from which to establish physicochemical characteristics (including toxicity and potency), processing parameters, and commensurate equipment set points. There is also a greater reliance on in-process monitoring and testing, and final product testing for Phase I, II, and possibly early Phase III clinical supply manufacture. This more intensive monitoring and testing is needed to supplant full process validation, where multiple batches have not been produced under replicated conditions. Once, as FDA puts it, “a growing body of scientific data and documentation” reaches a point, complete validation of the manufacturing process will be required.^[8]

While blending times and tablet press parameters may not be fully established for early phase clinical supply manufacturing of solid oral dosages, those variables have a much lower potential to directly affect product safety than sterility, endotoxin contamination, or objectionable types and levels of particulates do for sterile, parenteral clinical supplies.^[6] Because clinical supplies can be incompletely characterized, and are usually given to patients already in weakened conditions,^[7] those processes and their related validation data necessary to guarantee patient and product safety (e.g., sterilization and aseptic fill) are expected to be in place as early as Phase I clinical supply manufacture.^[6, 8]

Production and Process Controls

Written procedures are required to be established and followed for production and process controls as specified in 21 CFR Part 211.100. Because the specific requirements regarding handling of changes, deviations, and equipment

identification are addressed in other sections of this article, and all other provisions of Subpart F are required in order to meet CGMP requirements for clinical supplies, this section will focus on the other aspects of Subpart F that provide unique challenges during clinical supply manufacture.

Yield calculations are not only required according to 21 CFR Part 211.103, but they also provide some measure of process, phase, or step consistency when compared on a batch-by-batch basis. This information may prove useful when continuing process development, process optimization, or in the investigation of any process problems encountered during clinical supply production. Actual yields and percentages of theoretical yield also one of many important measures used to evaluate the validation of a manufacturing process.

Time limitations on production may not be fully known or established during early clinical supply development. However, those operations that are time-sensitive such as mixing or blending times, and drying times should be supported by data that are obtained through developmental studies. Arbitrarily assigning time limits without the benefit of any data, or the working knowledge of the operation in question, should be avoided, and can result in costly developmental errors and product delays.

Reprocessing can be defined as the repeating of a defined step or sequence of steps outlined in a master production and control record, in order to achieve a predetermined endpoint. Written procedures should be established and followed for any reprocessing steps or operations that are incorporated into a developed manufacturing process. The effectiveness of any reprocessing activity should be demonstrated through validation studies and should be fully supported by data.

Sterility Assurance

During inspections, FDA places a great deal of emphasis on the following systems they feel most directly will impact the safety and efficacy of sterile products manufactured,^[10] namely:

- Sterilization processes for the drug itself, any components, container/closures, product-contact equipment, and surfaces.
- Depyrogenation processes.^[11]
- Water systems.
- Air handling systems.
- Environmental monitoring programs.
- Handling of incoming components.
- Packaging and labeling operations.
- Laboratory controls.
- Lyophilization (if applicable).

In general, the above-mentioned, including procedures, systems and, if applicable, validation should be in place for clinical supply manufacturing operations. This would include validation of processes such as sterilization, depyrogenation, and lyophilization; qualification of water and air handling systems; establishing and following procedures for: environmental monitoring programs, handling of incoming components, packaging, and labeling operations; and CGMP compliance for laboratories performing analyses of raw materials, in-process and final product samples, environmental monitoring activities, and testing in support of clinical supply manufacturing. Additionally, those processes or activities that are product-specific (e.g., sterilization, depyrogenation, the manufacturing process for the finished drug product itself, and analytical testing related to raw materials, in-process and final product testing) should be validated to what has been previously noted as the “extent possible.” For example, in the case of sterilization processes such as terminal sterilization using moist heat, all of the following validation and process control requirements would be necessary in order to avoid exposing a patient to a risk of nonsterility:

- Equipment that is qualified, maintained, and calibrated.
- Empty chamber heat distribution studies.
- Heat penetration studies that are product and load pattern-specific.
- Challenges with biological indicators.
- Process controls and monitoring typical for steam sterilization (e.g., time, temperature, and pressure).^[6]

Similar logic can be applied to sterilization by filtration or depyrogenation by means of dry heat. In these and other cases, there will be little to no difference in the level of compliance necessary when comparing clinical supply manufacturing to that for the manufacturing for commercially approved products.

Change Control

Change control is one of the GMP systems that is applied somewhat differently in clinical supply manufacture than it is in the manufacture of commercial products. Change control does not have a separate and distinct section in the GMP regulations; however, the management of change is referenced or mentioned in several GMP sections [see, for example, 21 CFR 211.100(a) and 211.160(a)].

In commercial manufacturing, the purpose of change control is twofold:

1. Keep validated systems functioning in a validated state.

2. Maintain the accuracy of approved submissions to regulatory agencies (such as NDAs, ANDAs, BLAs, etc.).

In the manufacture of clinical supplies, normally, manufacturing processes are not robust (and therefore not completely validated) until Phase III, sometimes not until the later stages of Phase III. Therefore, the goals of change control in clinical supply manufacture are somewhat different. Those goals should include:

- Assurance that equipment (including computer systems and software), which has been qualified (installation, operational, and performance qualification), is maintained in a qualified state.
- Support systems (such as water for injection, air handling systems, compressed gases, vacuum, clean-in-place systems, and others) are likewise maintained in a qualified state.
- Any significant modification of the Chemistry, Manufacturing, and Controls section of the IND is noted, and, where applicable, the approved submission is supplemented to provide for the change.
- Key changes in the development of formulation, dosage form, manufacturing process, cleaning procedures, and other key operations are identified for the purpose of documenting them as part of the development history.
- When significant numbers of batches are manufactured using replicate processes (usually in late Phase III trials), changes are evaluated in order to determine if process development is complete, and validation should commence.

Laboratory Controls

The majority of 21 CFR 211.160 (laboratory controls) and subsections can be applied in the same manner for clinical supplies as for commercial products. An exception, in many cases, is the time by which analytical methods validation is required. For new chemical entities or significant formulation changes, new analytical methods may need to be developed. As with manufacturing processes, until such methods are robust it is difficult (or impossible) to validate them to the full extent that is expected for commercial products.

The factors normally considered in analytical methods validation include:

- Specificity.
- Sensitivity.
- Linearity.

- Repeatability.
- Robustness.
- Ruggedness.
- Limit of detection.
- Limit of quantitation.

Analytical method validation should track closely to the stages of development of the method itself. However, it is not realistic to expect complete and thorough validation of the method until its development cycle is complete. An exception to this would be a situation where an accepted compendial method is applied to clinical material (such as a dissolution test or release testing of a compendial component). In these cases, companies must be prepared to demonstrate that consistent acceptable results can be obtained when using the compendial method in the company's laboratory (also known as methods verification). The obvious difference is that a compendial method is not a proprietary method, having been developed fully in a collaborative process. Therefore, transfer of a compendial method to a clinical supply context does not differ from a similar transfer to a commercial product.

Methods for the investigation of out-of-specification (OOS) results should be similar to what is required for commercial manufacturing. However, it is recognized that in many cases, specifications may be less exact and methods may still be under development; therefore, it may be considerably more difficult to determine assignable causes for OOS findings related to clinical supplies.

When considering OOS investigation procedures for clinical supplies, manufacturers must keep certain basic principles in mind. Those basic principles include:

- OOS results must not be arbitrarily dismissed simply because they are unexpected and present obstacles to release of materials.
- Consideration must be given as to whether analyst error, equipment malfunction, inappropriate reagents, or some other detectable and assignable cause was the reason for an OOS result.
- Consideration must be given as to whether a detectable process error or nonprocess related (employee) error was the reason for the OOS result.
- There must be a documented rationale for resampling or retesting, including documentation of the reasonableness of the number of retests that are needed to overcome an OOS finding.
- Averaging of results should be avoided when the purpose of the test is to reveal variability in a batch (such as blend uniformity or content uniformity testing) because averaging tends to hide variability.

- If averaging is employed, OOS results must be included along with within-specification findings, unless they may be discarded by an approved statistical outlier test (either approved in the compendia or in the IND).

Training records for analysts should demonstrate that they have the necessary combination of education, training, and experience to perform the specific methods they are assigned to perform.

Stability testing will be guided mainly by the conditions approved in the IND. However, the manner in which the stability program is managed should be similar to that required for commercial products. For example (not an all inclusive list):

- Procedures to ensure that stability samples are correctly collected and are representative of the batch.
- Procedures to ensure that chambers are qualified (temperature mapped) and monitored for environmental parameters.
- Procedures to ensure that test intervals are consistently met.
- Procedures for the development of stability-indicating analytical methods.
- Complete, clear, and accessible records of all testing, including the preservation of raw data.

Deviations and Failure Investigations

As with commercial manufacturing, product or process deviations, or the failure of any clinical batch or any of its components to meet any of its specifications must be handled by approved procedures and thoroughly investigated (21 CFR 211.192). The investigation report should include, among other things:

- Nature of the deviation or failure.
- Date.
- Affected batch or batches.
- Root cause determination.
- Impact analysis.
- Recommended corrective actions.
- Approval by the Quality Unit.

Apart from being product or process-related, deviations can also be procedural in nature, meaning that certain requirements of a specific SOP were not adhered to. Sometimes the terms "unplanned" and "planned" deviations are also used. Unplanned deviations include those events, activities, or actions that are nonintentional. An example of an unplanned deviation could include shutdown of processing equipment during the manufacture

of a batch due to safety concerns. Planned deviation, on the other hand, is a term that is not favorably looked upon by FDA. A conscious decision not to follow written procedures, manufacturing instructions, or other records required under the predicate rule is, at the very least, a CGMP issue. The FDA expects that deviations will be fully and thoroughly documented, including any decisions made and by whom.

In the clinical supply setting, systems and procedures should be established and followed for handling deviations and performing investigations. For deviations, this would also include trending (either according to defined categories such as equipment, process, etc. by product line or other predefined criteria), timely resolution of the issues, and re-evaluation of process or equipment parameters and specifications, procedural requirements, or other items bearing on the quality or purity of the finished drug product. This re-evaluation is especially important during new product development, where less information may be known about the drug product being studied, the method of manufacture, process capabilities, or sensitivities of test methods. In these and other cases, improperly or incorrectly defined product or process attributes could contribute to an artificially high deviation rate, and more importantly, could suggest that additional product development work is needed.

Complaints and Adverse Reactions

Section 211.198 of the GMP regulations sets forth the requirements for reporting and investigating complaints. This section is intended to assure that when a manufacturer is notified of a product defect, a thorough investigation will be performed to determine the cause of the defect, and whether a recall of the product from the marketplace should be initiated. Of course, these activities are all aimed at protection of patients from harm caused by defective products.

When the product in question is intended only for use in clinical trials, the fundamental purpose of the regulation, protection of patients from defective products, must still be of primary concern. However, the quantity of product at risk, and its limited distribution will impact the process of complaint investigation. For example, the generally smaller amount of product involved may make it difficult to identify low-level occurrences of manufacturing defects. The limited and more tightly controlled system of distribution of clinical trial supplies, however, will likely facilitate and limit the recall process should that be deemed necessary.

Complaints of adverse reactions to clinical supplies are typically seen as reportable events that impact the safety or

efficacy of the test article. Companies should give consideration to the possibility that an increase in the frequency or severity of adverse reactions may be linked to a manufacturing defect. For example, a product that has been formulated such that it is superpotent in its final form can be expected to produce adverse reactions of greater severity or frequency than if it was properly formulated. Labeling mix-ups can have devastating impact on patients, or, at minimum, may seriously affect the validity of a clinical trial. Therefore, the following elements should be included in the complaint assessment system:

- Complaints of observable (physical) defects should be promptly and thoroughly investigated to determine the root cause of the defect and the probable scope of its occurrence.
- Complaints of unusual or severe adverse reactions, or significant and unexpected increases in the number of adverse reactions (including marked lack of efficacy) should be evaluated to determine whether manufacturing errors may have caused or contributed to the observed effects.
- When a product defect is identified, the evaluation should include a health hazard assessment by a qualified person, usually a physician. The FDA's recall policy regulations contain a suggested rubric for performing a health hazard assessment (see 21 CFR 7.41).
- Product defect complaints and adverse reaction data and trends should be periodically compared to determine if there is any correlation between unexpected numbers, types or severity of adverse reactions, and the number and type of reported product defects.
- As with commercial products, careful records of reported complaints, their investigation and resolution are critical to GMP compliance.

Technology Transfer Plans and Reports

Technology transfer plans and reports are used by a research and development organization in order to document their official "transfer" of a newly developed or recently upgraded product/process from the developmental area and facilities to an operations unit and site, usually located in separate buildings, or at an entirely separate and different manufacturing sites. While the format and content has not been formally prescribed by FDA, companies generally include the following information^[12] in these documents:

- Definition of responsibilities for key departments; documentation review, approval, and storage requirements.
- Summary of developmental activities completed.

- Summary of scale-up activities; summary of formulation, synthesis, process, and analytical method changes; establishment of impurity specifications; establishment of critical process parameters; identification of validation plans and activities.
- Definition of component, container/closure, and product attributes.
- Analytical methods development and validation summary.
- Descriptions, specifications, design parameters and requirements of facilities, and major equipment and utility systems.
- Definition of the manufacturing process.
- Stability and expiry dating information.
- Change control.
- Reprocessing.
- Cleaning processes, including methods development and validation of the processes and methods.
- Summary of Regulatory Affairs activities, including regulatory commitments, key data and information to be summarized in regulatory filings.

Data Integrity Considerations

The integrity of GMP data should be a vital part of any company's compliance scheme. The term "data integrity" generally means that the raw (source) data and associated data summaries and reports are truthful, accurate, legible, indelible, complete, and readily accessible. This applies whether the data are in hard copy (paper) form or electronic form. The GMP rules allow for the preservation of data through photocopying or other optical reproduction process (microfilming, optically scanning, etc.); however, original documents should be preserved whenever possible.

The fundamentals of good data recording practices should be observed in clinical supply manufacturing in exactly the same manner as required for commercial materials. Those fundamentals include the following:

- Data, and the identification of those responsible for it, should be recorded contemporaneously, or as close to the time of execution of a step or an observation as is practical. Transfer of data from one form to another should be minimized, and should include one hundred percent verification for accuracy by a second person. This serves to enhance the accuracy of the data.
- Hard copy documents should be recorded in indelible ink. Errors are inevitable, and when they occur, the original entry should be struck out with a single line, initialed and dated, the correct information entered, and a brief explanation of the error should be appended

as directed by the document and associated procedures.

- Data should always be recorded on forms designed for the specific purpose. Extraneous notations on loose slips of paper (including post-it notes, scrap paper, paper towels, etc.) should be strictly prohibited in a GMP environment.
- Log books, laboratory notebooks (when used), batch production and control records, qualification and validation protocols and reports, investigations of deviations and failures, and other GMP documentation must be carefully identified, controlled, and archived in a manner that will facilitate its prompt retrieval.
- Electronic records (and electronic signatures, if used) must comply with the provisions of 21 CFR Part 11. It is beyond the scope of this article to explain "Part 11" compliance in total, however, the general principle is to construct and maintain electronic records with the same degree of accuracy and linkage to the originator as is achieved with hard copy documents. Each company choosing to use electronic data capture techniques and electronic signatures must thoroughly understand Part 11 and ensure compliance with this regulation.
- Each company should have a policy that strictly prohibits the deliberate falsification, mutilation, obliteration, or destruction of raw data and associated GMP documentation. Companies must insist on strict adherence to such policies and should take aggressive disciplinary action when lapses are detected. Failure to do so may subject the company and its corporate officers to severe regulatory sanctions, including criminal prosecution under the Federal Food, Drug, and Cosmetic Act, or the general criminal laws of the United States (Title 18, U.S. Code). Even inadvertent (non deliberate) acts that result in loss of data or records should be prevented, and, if they occur, they should be promptly and thoroughly investigated.
- Establishing and following policies and procedures for good documentation practices, numerical rounding, significant figures, and directed audits to ensure the integrity of data contained in records or other documents prior to submission of applications to FDA).

CLINICAL PHARMACOKINETICS AND PHARMACODYNAMICS

Leslie Z. Benet
Laviero Mancinelli

University of California San Francisco, San Francisco, California, U.S.A.

INTRODUCTION

Therapeutics relates drug administration to physiological effects, both beneficial and toxic, in patient populations. The important intervening steps or processes, which occur following drug dosing that lead to therapeutic effects in the body, are described in Fig. 1. This scheme illustrates the dose-effect relationship. The discipline of pharmacokinetics provides an understanding of drug absorption, disposition, and elimination, as these relate to the physiological effects of drugs. Pharmacodynamics relates the measured response, either efficacious, toxic, or both, to the drug's pharmacokinetics. Pharmacokinetics has become increasingly important, as it has proven to be a very useful tool in understanding not only drug dosage in relation to achievable drug concentrations in plasma, but also the influence of disease states on the behavior of a drug in the body. A very powerful interpretative instrument becomes available when the disciplines of pharmacokinetics and pharmacodynamics are combined. Clinical pharmacokinetics specifically deals with optimizing drug dosage in individual patients. By using plasma concentration measurements, and clinical pharmacokinetic principles, doses can be adjusted to achieve maximal therapeutic utility, with minimum toxic risks for individual patients.

Basic knowledge of pharmacokinetic principles is important not only for the clinician to understand basic drug-patient interrelationships, but also for the drug industry to facilitate the design of relevant studies for drug discovery candidates. The gain from designing proper pharmacokinetic studies can probably be counted not only in better therapy for the patient but also in long-term economic savings for the pharmaceutical industry.

In this article the basic principles of pharmacokinetics and pharmacodynamics will be addressed, and examples of how these principles can be used to increase the understanding of drug therapy and drug dosage formulation are given.

PHARMACODYNAMIC CONSIDERATIONS

The fundamental hypothesis in clinical pharmacokinetics asserts that a relationship exists between a drug concentration in some measurable biologic fluid and observed drug effects, both therapeutic and/or toxic, as illustrated in Fig. 1. Many drugs, for example, antiarrhythmics, anticonvulsants such as phenytoin, and diuretics such as furosemide, show an apparent direct relationship; that is with every change in plasma drug concentration, there is an immediate and corresponding change in effect. For other drugs the relationship is more complicated; the drug level of warfarin for instance, triggers a cascade of events leading to prolonged clotting time. Here, the mean steady-state level rather than the time course of concentrations can be most closely correlated to the therapeutic effect. In some instances, the effect itself is difficult to quantify, and demonstrating any relationship is difficult. When unbound concentrations are maintained at a particular steady-state concentration across a population, then an observed difference in response between individuals must be due to pharmacodynamic receptor-level variability across the population. However, most traditional relationships of drug effects have been developed relative to drug dose rather than steady-state unbound concentrations. When comparing the dose given to the effect, the variability in drug absorption, first-pass metabolism, protein binding, and clearance must also be included, thereby giving a significantly more variable and complicated relationship.

The full model for the concentration (C) and effect (E) relationship is the Hill equation, also called the extended E_{\max} model (1):

$$E = \frac{E_{\max} C^s}{EC_{50}^s + C^s} \quad (1)$$

where E_{\max} is the maximal effect, EC_{50} is the concentration giving 50% of maximal effect, and s is the slope factor. The Hill equation can be simplified to different extents, for example, if $s = 1$.

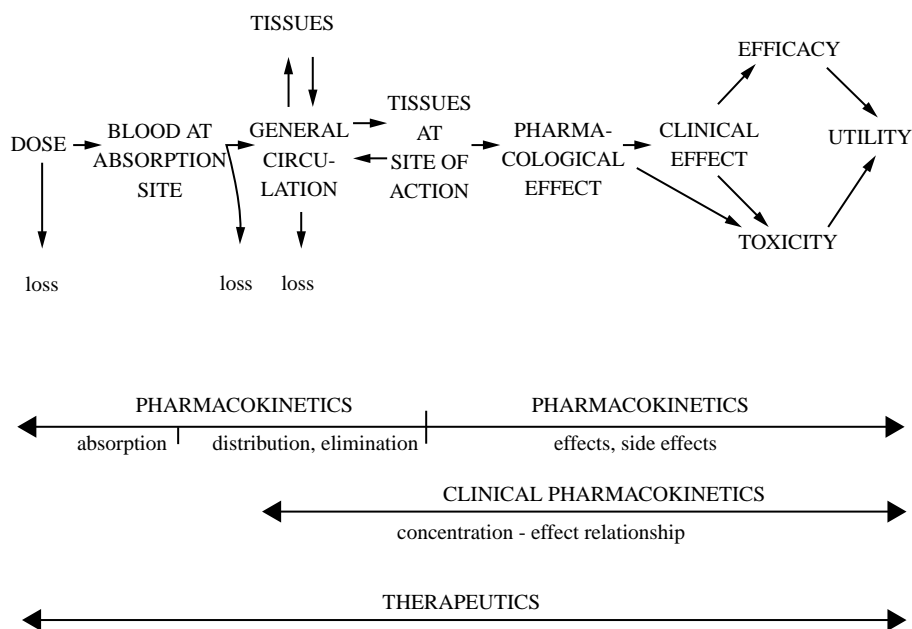

Fig. 1 Schematic representation of the dose-effect relationship for a drug.

Between 20 and 80% of the maximal response, the relationship is logarithmic:

$$E = m \log C + e \quad (2)$$

where m is the slope and e is the intercept. This equation has the limitations of not being able to predict effects outside this range of responses (i.e., <20% and >80%).

Below 20% of maximal response, the relationship is linear:

$$E = mC + e \quad (3)$$

This relationship has been used for up to 50% of maximal response; however, it then is a coarse approximation, depending upon the value of s (the lower the value of s , the better the approximation).

The Hill equation should be used only when a reasonable estimation of E_{\max} is possible and when data are gathered over the whole effect range. If data are available only from the lower part of the curve, the linear equation might just as well be used. The difference between the Hill equation and the linear or log-linear equation is that only the Hill equation gives a mechanistic-physiologic understanding of the effect. The other equations are merely descriptive.

Sheiner and associates (2) have developed the relationship where the pharmacodynamic model (Eq. 1) is integrated together with the pharmacokinetic model. This makes possible describing both the steady-state

concentration-effect relationship (i.e., EC_{20} , EC_{50} , EC_{90} , etc.) and the time lag between the measured rapidly changing plasma concentration and the corresponding steady-state effect at that concentration level. This time-lag parameter is described by the equilibration half-time. Using both these parameters, that is, the expected effect and the time required to obtain the effect, allows investigators to model the effect-concentration relationship when patients are not at steady state.

The relationship between the measured effect and steady-state plasma concentration sometimes yields bell-shaped (e.g., nortriptyline) or U-shaped (e.g., clonidine) curves. Several unusual concentration-effect curves, including the U-shaped curve describing the blood pressure lowering effect of clonidine, have been explained by Paalzow and associates (3) as being a result of multiple receptor responses. The drug then acts on several different receptors that can have opposite effects and that are triggered at different concentrations.

Tolerance to the drug effect, that is, a decrease in the effect with time, also obscures the dose-response relationship. Pharmacokinetic and/or pharmacodynamic causes for tolerance development are possible. Pharmacokinetic tolerance, for example, can be caused by induction of metabolic enzymes, thereby causing a decrease in drug concentrations. Pharmacodynamic tolerance can be characterized mainly in two different ways: the receptors down-regulate in response to the drug, giving a smaller response with time, or other physiologic

mechanisms counteract the drug effect. The blood pressure lowering effect of hydralazine that is diminished by a compensatory increase in heart rate, and the diuretic effect of furosemide that is decreased as a result of the drug's volume and salt-depleting actions are two examples.

Fig. 2 illustrates a utility curve, that is, a curve describing the clinical utility of a drug in terms of the risk of side effects from a high concentration and the risk of no effect from a low concentration. The closer the effect and toxicity curves, the more narrow is the range of plasma concentrations that can be used for therapy. The utility is obtained as the difference between the effect and toxicity.

Depending upon the steepness of the concentration–effect relationship (the size of s in Eq. 1), an increase in concentration will result in different changes in effect. An all-or-none relationship is obtained when the curve is very steep ($s > 6$). Theophylline shows a shallow relationship with plasma concentration for its antiasthmatic effect; a big increase in concentration results in a small increase in effect. However, as the side effects of theophylline show a much steeper relationship with plasma concentration, it is critical not to increase theophylline concentrations above 20 mg/L. With a lower limit for antiasthmatic effect of

10 mg/L, theophylline exhibits a narrow range of concentrations where therapy is beneficial.

Another measure of utility is in terms of the ratio between the concentration level causing an undesirable side effect to the concentration level giving the desired therapeutic effect (therapeutic index). For theophylline this ratio is 2, for digoxin it is 1.6, and for furosemide it is 40. The higher the therapeutic index, the less critical are dosing recommendations with respect to the risk of serious side effects.

CLEARANCE

Clearance is the measure of the ability of the body to eliminate a drug, and as such is one of the most important pharmacokinetic parameters, as it gives a well-defined, physiologically relevant measurement of how drugs are eliminated by the organism as a whole, or by a particular organ. Clearance relates drug concentration to the elimination rate from the body (Eq. 4), or at steady state the average concentration C_{ss} to the dosing rate because at steady state the input rate into the body will equal the output rate (Eq. (5)):

$$\text{Elimination rate} = CL C \quad (4)$$

$$\text{Dosing rate} = CL C_{ss} \quad (5)$$

The clearance concept has been used in defining the pharmacokinetics of drugs since the mid-1970s (4, 5). The clearance concept is based in physiology, where it is used as a measure of renal function (creatinine clearance). Creatinine is formed from muscle breakdown at a constant rate, and thus a constant creatinine concentration in plasma results. The magnitude of this concentration is dependent on the elimination rate of creatinine and the size of the muscle pool (formation rate). By measuring the plasma concentration and the renal excretion of creatinine, renal clearance can be estimated and thereby kidney function indicated, as creatinine is mainly filtered into the urine

$$CL_{\text{creatinine}} = \frac{\text{Urine volume} \times \text{Urine concentration}}{\text{Plasma concentration}} \quad (6)$$

Drugs are not only eliminated via the kidneys but also eliminated in the bile by the liver and metabolized in the liver and elsewhere, which makes direct measurement of the elimination rate of a drug difficult. Indeed, other routes of elimination could include loss in expired air, saliva, sweat, partition into tissue stores, efflux from the blood into the gut lumen, and gut metabolism as well as

Fig. 2 Utility curve and concentration–effect/toxicity relationships for a theoretical drug according to Eq. (1). EC_{50} for efficacy = 10 mg/L, EC_{50} for toxicity = 60 mg/L, thus the therapeutic index is 6; $s = 1.0$. Utility is obtained as the difference between effect and toxicity.

other sites of metabolism such as the lung. The total clearance, CL, can be defined as

$$CL = \frac{\text{Dose}_{i.v.}}{\text{AUC}} \quad (7)$$

where $\text{Dose}_{i.v.}$ is the intravenous dose, and AUC is the resulting area under the plasma concentration time curve. Total clearance can also be measured during continuous drug therapy as dosing rate divided by C_{ss} according to Eq. 5.

Clearance is referenced to plasma (plasma clearance, CL_p), blood (blood clearance, CL_b) or plasma water (unbound clearance, CL_u), depending upon where the concentration is measured. Total clearance can be divided into the contributions of each of the eliminating organs, the most important being renal clearance, CL_R , and hepatic clearance, CL_H .

$$CL = CL_R + CL_H + CL_{\text{gut}} + CL_{\text{other}} \quad (8)$$

Renal clearance can be separately determined by measuring the excretion rate of unchanged drug into the urine, as for creatinine. The difference between total clearance and renal clearance is usually called *nonrenal clearance*, meaning the clearance that is not accounted for by excretion of unchanged drug into urine, be it metabolism in the liver or elimination by any other organ.

Clearance is measured in units of volume per time (ml/min or L/h) and thus is defined using the same units as blood or plasma flow. By definition, clearance gives the volume of plasma (blood) from which a drug is completely removed per unit time. For some drugs the liver or kidneys have the ability to clear drug from all the blood flowing through the organ; for example, *p*-aminohippuric acid (PAH) has a renal plasma clearance of 600–700 ml/min, which equals renal plasma flow. Because PAH does not partition into red blood cells, PAH renal blood clearance will equal renal blood flow (see imipramine in the next paragraph for calculations according to Eq. 9, $C_{RBC}/C_p = 0$). So, when the eliminating organ has a high capacity to eliminate a drug, the blood clearance equals the blood flow to that organ. As the organ cannot eliminate drug any faster than the rate at which drug is presented to the organ, blood flow becomes the limiting value for clearance. Thus, hepatic blood clearance cannot exceed 1.5 L/min, and renal blood clearance cannot exceed 1.2–1.3 L/min.

Some drugs show a higher plasma clearance than the corresponding plasma flow through the eliminating organ. Imipramine has a plasma clearance of 1050 ml/min (6), thus exceeding the rate of plasma flow to the liver, where it is predominantly eliminated. Looking at whole blood, the concentration of imipramine in blood is higher than its concentration in plasma because of a considerable

partitioning into red blood cells ($C_{RBC}/C_p = 2.7$). Thus, the amount of drug delivered to the liver by the blood is much higher than that assumed from measuring its plasma concentration alone. The relationship between plasma and blood clearance at steady state is given by

$$\frac{CL_p}{CL_b} = \frac{C_b}{C_p} = 1 + H \left(\frac{C_{RBC}}{C_p} - 1 \right) \quad (9)$$

Imipramine blood clearance can be calculated by substituting the red blood cell to plasma concentration ratio and the average value for hematocrit ($H = 0.45$) into Eq. 10). The resulting blood clearance is calculated to be 595 ml/min, a value within the physiologic range of liver blood flow. The higher plasma versus blood clearance for imipramine also indicates that the drug present in the red blood cells is readily available for the metabolizing enzymes by being in rapid equilibrium with the drug present in plasma water. Thus, the plasma clearance may assume values that are not “physiologic.” However, if the concentration in blood is used to define clearance, the maximal clearance possible is equal to the sum of blood flow to the various organs of elimination. If a drug shows a higher blood clearance than the combined blood flow, a probable cause is extrahepatic or extrarenal elimination, such as the metabolism of nitroglycerin in blood and tissues. The *rate of elimination* of a compound by an organ is the difference between the rate of presentation to the organ and the rate of exit from the organ. *Rate of presentation* equals the organ blood flow multiplied by the entering concentration (QC_{in}), and the *rate of exit* equals the blood flow multiplied by the exiting drug concentration (QC_{out}) (Fig. 3).

$$\text{Rate of elimination} = QC_{in} - QC_{out} \quad (10)$$

By relating the rate of elimination to the entering concentration (Eq. 4), an expression for organ clearance of drug can be obtained

$$CL_{\text{organ}} = \frac{Q(C_{in} - C_{out})}{C_{in}} = QER \quad (11)$$

in terms of blood flow and ER, the extraction ratio, which equals $(C_{in} - C_{out})/C_{in}$. A high organ clearance signifies that the organ has a high capacity to extract drug from the blood.

For a compound for which the organ has a high extraction capacity, the exiting concentration is very low relative to the entering concentration, and ER approaches unity. For an organ with a low extraction capacity, the exiting concentration is not very different from the entering concentration, and ER approaches zero. Extraction ratio can thus be expressed as the fraction of the organ blood flow

Fig. 3 Extraction of drug in an organ of elimination.

that is cleared by the organ ($ER = CL_{\text{organ}}/Q_{\text{organ}}$). Several models relating the hepatic clearance to physiologic parameters have been suggested, including the well-stirred and the parallel tube models (7, 8), the distributed model (9, 10), and the dispersion model (11–14). The well-stirred model is the most easily understood and most commonly employed model, and the following discussion will be based on this approach.

The well-stirred model assumes that the unbound drug concentration leaving the organ, for example the liver, is equal to the unbound concentration within the organ, thus assuming an instant “mixing” at the entrance of drug into the organ. The intrinsic ability to metabolize or otherwise clear unbound drug and the protein binding (unbound fraction, f_u) together with the blood flow through the liver (Q_H) all contribute to the resulting hepatic clearance, which may be mathematically expressed as

$$CL_H = Q_H \frac{f_u CL_{u,\text{int}}}{Q_H + f_u CL_{u,\text{int}}} \quad (12)$$

Thus, an example of a high-extraction drug is when the capacity of the liver to metabolize a drug is large compared to the rate at which drug enters the liver ($f_u CL_{u,\text{int}} \gg Q_H$), clearance approximates liver blood flow

$$CL \cong Q_H \quad (13)$$

An example of low-extraction drug is when the capacity of the liver to metabolize a drug is small relative to the rate of presentation ($f_u CL_{u,\text{int}} \ll Q_H$), because of a low intrinsic ability to metabolize or because of diffusion problems to the enzyme site. Under these conditions, hepatic clearance approximates

$$CL \cong f_u CL_{u,\text{int}} \quad (14)$$

Between these extremes, hepatic clearance is dependent on all three factors: Unbound fraction of drug, intrinsic

clearance, and hepatic blood flow. The unbound clearance, CL_u , equals CL/f_u .

A reasonable assumption is that the active secretion mechanism in the kidney can also be described by the well-stirred model. However, the kidneys have several mechanisms that may determine renal clearance of a drug, including passive filtration and reabsorption.

The renal clearance is the sum of filtration and secretion minus reabsorption. It can be described as

$$CL_R = CL_{\text{filtration}} + CL_{\text{secretion}} - CL_{\text{reabsorption}} \quad (15)$$

or,

$$CL_R = (CL_{\text{filtration}} + CL_{\text{secretion}}) (1 - \text{fraction reabsorbed}) \quad (16)$$

Filtration in the kidneys is determined by the glomerular filtration rate, GFR (120 ml/min in a healthy young person), and by the fraction of the drug that is dissolved in plasma water, that is, the unbound fraction, f_u . Thus,

$$CL_{\text{filtration}} = f_u \text{ GFR} \quad (17)$$

Suppositions regarding the mechanisms by which a drug is renally eliminated can be made by comparing the filtration clearance with the measured renal clearance. Drug is always passively filtered to some extent, depending of the value of f_u . If $CL_R > CL_{\text{filtration}}$, the drug is also secreted and may be reabsorbed but to a smaller extent than it is secreted. If $CL_R < CL_{\text{filtration}}$, however, this is an indication of reabsorption but does not exclude secretion. If $CL_R = CL_{\text{filtration}}$, the drug can still be both secreted and reabsorbed, but to the same extent. Conclusive evidence on whether a drug is reabsorbed cannot be made solely on the basis of clearance values.

Intestinal Metabolism or Clearance

Recently, it has been recognized that small intestinal metabolism and active efflux of orally absorbed drugs, are major determinants of oral drug bioavailability (15). Many elements, including patient specific ones, determine the extent of oral drug delivery. The observed oral bioavailability (F_{oral}) of any particular drug is dependent upon the following processes: delivery to the intestine (gastric emptying, pH, presence of food), absorption from the lumen of the intestine (dissolution, lipophilicity, particle size, active uptake), intestinal metabolism (phase I/phase II), active extrusion (drug efflux pumps), and then first pass hepatic metabolism (16).

The enzymes of the cytochrome P 4503A family are the predominant phase I drug metabolizing enzymes in man. The major isoform of the CYP3A family is CYP3A4, the

predominant form found in adult human liver and small intestine. Members of the 3A4 family are estimated to be responsible for the metabolism of more than one half of all drugs that are substrates for the P450 system of metabolic enzymes in man (17). The levels of CYP3A4 found in human liver and small intestine is highly variable, with 10–100 fold variations observed in liver and as much as 30-fold variation in the small intestine, respectively (18). Levels of CYP3A4 in the small intestine are generally 10–50% of the levels found in the human liver, and these levels as well as the activity of the enzyme decrease longitudinally along the small intestine (19). The enzymes of the CYP3A4 subfamily comprise approximately 30% of all hepatic cytochromes and at least 70% of all intestinal cytochromes responsible for drug metabolism (20).
